TO

MY MOTHER

THIS VOLUME IS AFFECTIONATELY
DEDICATED

PREFACE TO THE FIRST EDITION

It is hoped that this small volume may fill a want in the already crowded field of medical monographs. The author has endeavored to give to the general practitioner a readable, authoritative essay on a disease which is especially an outcome of modern civilization. To that end all the available literature has been freely consulted, and the newest results of experimental research and the recent ideas of leading clinicians have been summarized. The author has supplemented these with results from his own experience, but has thought it best not to burden the contents with case histories.

The stress and strain of our daily life has, as one of its consequences, early arterial degeneration. There can be no doubt that arterial disease in the comparatively young is more frequent than it was twenty-five years ago, and that the mortality from diseases directly dependent on arteriosclerotic changes is increasing. Fortunately, the almost universal habit of getting out of doors whenever possible, and the revival of interest in athletics for persons of all ages, have to some extent counteracted the tendency to early decay. Nevertheless, the actual average prolongation of life is more probably due to the very great reduction in infant mortality and in deaths from infectious and communicable diseases.

The wear and tear on the human organism in our modern way of living is excessive. Hard work, worry, and high living all predispose to degenerative changes in the arteries, and so bring on premature old age. The author

has tried to emphasize this by laying stress on the prevention of arteriosclerosis rather than on the treatment of the fully developed disease.

No bibliography is given, as this is not intended as a reference book, but rather as a guide to a better appreciation and understanding of a most important subject. It has been difficult to keep from wandering off into full discussions of conditions incident to and accompanied by arteriosclerosis, but, in order to be clear in his statements and complete in his descriptions, the author has to invade the fields of heart disease, kidney disease, brain disease, etc. It is hoped, however, that these excursions will serve to show how intimately disease of the arteries is bound up with diseases of all the organs and tissues of the body.

Some authors have been named when their opinions have been given. Thanks are extended also to many others to whom the writer is indebted, but of whom no individual mention has been made.

The author also takes this opportunity of expressing his appreciation of the kindness of Dr. D. L. Harris, who took the microphotographs, and to the publishers for their unfailing courtesy and consideration.

Louis M. Warfield.

St. Louis, August, 1908.

PREFACE TO THE SECOND EDITION.

In this second edition so many changes and additions have been made that the book is practically a new one. All the chapters which were in the previous edition have been carefully revised. Two chapters, "Pathology" and "Physiology," have been completely rewritten and brought up to date. It was thought best to add some references for those who had interest enough to pursue the subject further. These references have been selected on account of the readiness with which they may be procured in any library, public or private. Two new chapters have been added—one on "The Physical Examination of the Heart and Arteries," the other on "Arteriosclerosis in Its Relation to Life Insurance," and it is hoped that these will add to the practical value of the book.

Arteriosclerosis can scarcely be considered apart from blood pressure, and in the view expressed within, with which some may not concur, high tension is considered to be a large factor in the production of arteriosclerosis. As the data on blood pressure have increased, the importance of it has become more evident. The chapter on "Blood Pressure" has been wholly rewritten, expanded so as to give a comprehensive grasp of the essential features, and several illustrations have been added in order to elucidate the text more fully. The chief objects in view were to make clear to the physician the technique and the necessity for estimating both systolic and diastolic pressures.

The author is grateful for the kindly reception accorded the first edition. No one is more keenly aware of the im-

perfections than he. The necessity for a second edition is taken to mean that the book has found a place for itself and has been of use to some.

The author hopes that this new edition will fulfill adequately the purpose for which he prepared the book—namely, as a practical guide to the knowledge and appreciation of a most important and exceedingly common disease.

LOUIS M. WARFIELD.

Milwaukee, May, 1912.

INTRODUCTION.

By William Sydney Thayer, M.D.

There is a despotism to which the greater part of mankind is enslaved, a despotism as absolute in the republic as in the autocracy—the tyranny of words. The thought or fancy, unexpressed, may have its passing influence; expressed, the mere sound of our own voice exercises upon us a subtle influence which, as it were, drives home the idea, while repetition fastens upon us an impression which, before we are aware of it, has become a conviction—a part of ourselves.

A term which strikes the popular ear becomes soon associated, in the mind of the average individual, with an idea or a picture which may vary greatly from that of his neighbor, and more yet from the truth. Nevertheless time and repetition fix the idea until it is difficult to realize that the word has not to every one the same constant and sharply defined signification.

The prevalence of such popular words and expressions in medicine is familiar to all. These vary greatly in character and origin. Those of older years were usually expressions intended to describe certain groups of clinical symptoms, and were based largely on purely hypothetical considerations. These terms must, of necessity, have been rather indefinite and uncertain in their application even among the medical profession, and much more so among the general public. Such is that commonest and most detestable of words which means everything to everybody

and nothing under the sun in itself, "biliousness." Such has been the term "malaria" in its popular sense. Such is, often enough, the all too popular word "rheumatism." In more modern times, with the development of knowledge of pathological anatomy and physiology, more accurate terms have come into medicine—some based on anatomical, some on physiological changes. Many of these terms have also passed over into popular usage. And while, originally, they designated specific anatomical conditions or physiological processes, the uninstructed public associate them naturally with groups of symptoms, and form many and varied ideas as to their significance. But to each individual the words mean something.

All this has too often its repercussion on the physician who, in order to satisfy his patients who demand a name for the symptoms from which they suffer, is led, almost unconsciously, to use a specific term in a general way to cover a variety of conditions in which perhaps the exact diagnosis may not be wholly clear, until, by force of habit and repetition, he finds a certain satisfaction in hiding behind an empty term, and becomes himself a victim of the tyranny of words. What an array of pathological processes has been dismissed under the specific diagnosis of "gastritis" or "neuritis"!

The study of those changes in the blood vessels—hyperplastic, degenerative, or inflammatory—which are the inheritance of advancing years, and have been so aptly called "the rust of life," is not new. The term "arteriosclerosis" was used anatomically by Lobstein three-quarters of a century ago, and the relations of arterial change to visceral disease have long been a fertile field for speculation and study. But the popularization of the term "arteriosclerosis" from a clinical standpoint is relatively recent. In later years, however, it has definitely caught

the popular ear; it figures in the newspapers as a "new disease"; it means something to each member of the public; it is a diagnosis satisfying to the anxious friends of the patient. And, too often, the general diagnosis "arteriosclerosis" has come to satisfy the physician himself who, without finding a definite explanation of the obscure symptoms of his patient, rests on his oars with the constatation of the tortuous temporal or the palpable radial of the sufferer. The term "arteriosclerosis" is fast coming to take a place near the throne once occupied by "malaria"—it is becoming a dangerous word.

Great as is the importance of arterial changes in relation to many of the ills to which flesh is heir, and numerous as have been the anatomical, clinical, and experimental researches concerning this subject, it must be acknowledged that there is much yet to be learned with regard to the etiology, the manner of development, the nature of the changes in different parts of the arterial tree, their relation to variations in blood pressure and to visceral disease, as well as concerning the relations of peripheral to central changes; and there are still wide differences of opinion as to the interpretation of some of the observations which have been made.

In view, therefore, of these considerations, as well as of the widespread and indiscriminate popular use of the term "arteriosclerosis," the time would seem to be peculiarly fitting for the publication of a brief and practical consideration of the present state of our knowledge concerning the nature and clinical bearings of arterial disease, such as that which my friend, Dr. Warfield, seeks to set forth.

There can be no doubt that we Americans are prone to waste our energies. We do not know how to rest or to conserve our strength; and it is probably true, as Dr. War-

field suggests, that the wear and tear of this feverish and unreasoning activity leaves, too often, an early mark on the cardiovascular system.

It should, as he has said, be the earnest endeavor of the physician to prevent the premature development of these vital changes rather than to seek to alleviate symptoms after irreparable damage has been done.

ARTERIOSCLEROSIS.

CHAPTER I.

ANATOMY.

With the increased complexity of our modern life comes increased wear and tear on the human organism. "A man is as old as his arteries" is an old dictum, and, like many proverbs, the application to mankind today is, if anything, more pertinent than it was when the axiom was first uttered. Notwithstanding the fact that the average age of mankind at death has been materially lengthened—the increase in years amounting to fourteen in the past one hundred years of history—clinicians and pathologists are agreed that the diseased condition known as arteriosclerosis is present to an alarming extent in persons over forty years of age. The great group of cases of which cardiac incompetence, aneurysm, cerebral apoplexy, chronic Bright's disease, emphysema, and chronic bronchitis are the most frequent and important appear as terminal events in which arteriosclerosis has played the primary part.

Thus, in the sense in which we speak of tuberculosis or diabetes as a distinct disease, we can not so designate the diseased condition of the arteries. The manifestations are multiform, and yet it is convenient to treat the many protean types included under the heading arteriosclerosis as a particular disease. We shall, therefore, consider arteriosclerosis as a distinct disease rather than as a symp-

tom group, for, from a clinical standpoint, there is much in favor of regarding it as an entity.

Definition.

Arteriosclerosis (called by some arteriocapillary fibrosis, by others atherosclerosis) may be defined as a chronic disease of the arteries and arterioles, characterized anatomically by increase or decrease of the thickness of the walls of the blood vessels, the initial lesion being a weakening of the middle layer caused by various toxic or mechanical agencies. This weakness of the media leads to secondary effects, which include hypertrophy or atrophy of the inner layer—and not infrequently hypertrophy of the outer layer—connective tissue formation and calcification in the vessels, and the formation of minute aneurysms along them. The term arteriocapillary fibrosis has a broader meaning, but is a cumbersome phrase, and conveys the idea that the capillary changes are an essential feature of the process, whereas these are for the most part secondary to the changes in the arteries. The veins do not always escape in the general morbid process, and when these are affected the whole condition is sometimes called vascular sclerosis or angiosclerosis.

Upon the anatomical structure of the arteries depends, as a rule, the character and extent of the arteriosclerotic lesions. For the clear comprehension of the process, it is necessary to keep in mind the essential histological differences between the aorta and the larger and smaller branches of the arterial tree.

The vascular system is often likened to a central pump, from which emanates a closed system of tubes, beginning with one large distributing pipe, which gives rise to a series of tubes, whose number is constantly increasing at the

same time that their caliber is decreasing in size. From the smallest of these tubes, larger and larger vessels collect the flowing blood, until, at the pump, two large trunks of approximately the same area as the one large distributing trunk empty the blood into the heart, thus completing the circle. This is but a rough illustration, and, while possibly useful, takes into account none of the vital forces which are constantly controlling every part of the distributing system.

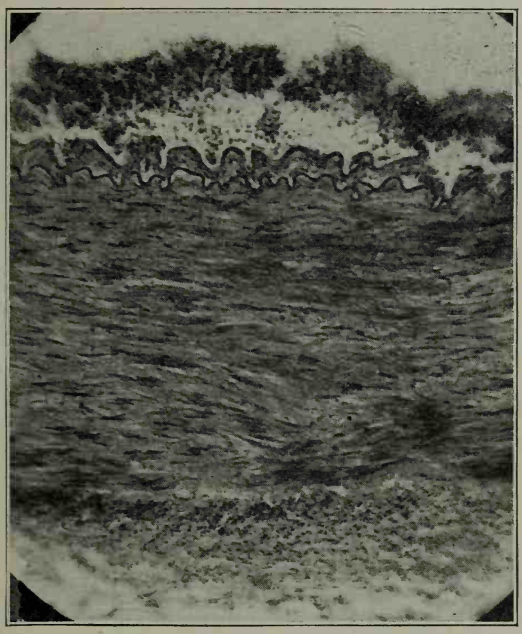

Fig. 1.—Cross-section of a large artery showing the division into the three coats; intima, media, adventitia. The intima is a thin line composed of endothelial cells. The wavy elastic lamina is well seen. The thick middle coat is composed of muscle fibers and fibro-elastic tissue. The loose tissue on the outer (lower portion of cut) side of the media is the adventitia. (Microphotograph, highly magnified.)

General Structure of the Arteries.

The aorta and its branches are highly elastic tubes, having a smooth, glistening inner surface. When the arteries

are cut open, they present a yellowish appearance, due to the large quantity of elastic tissue contained in the walls. The elasticity is practically perfect, being both longitudinal and transverse. The essential portion of any blood vessel is the endothelial tube, composed of flat cells cemented together by intercellular substance and having no stomata between the cells. This tube is reinforced in different ways by connective tissue, smooth muscle fibers, and fibro-elastic tissue. Although the gradations from the larger to the smaller arteries and from these to the capillaries and veins are almost insensible, yet particular arteries present structural characters sufficiently marked to admit of histological differentiation.

The whole vascular system, including the heart, has an endothelial lining, which may constitute a distinct inner coat, the tunica intima, or may be without coverings, as in the case of the capillaries. The intima (Fig. 1) consists typically of endothelium, reinforced by a variable amount of fibro-elastic tissue, in which the elastic fibers predominate. The tunica media is composed of intermingled bundles of elastic tissue, smooth muscle fibers, and some fibrous tissue. The adventitia or outer coat is exceedingly tough. It is usually thinner than the media, and is composed of fibro-elastic tissue. This division into three coats is, however, somewhat arbitrary, as in the larger arteries particularly it is difficult to discover any distinct separation into layers.

The muscular layer varies from single scattered cells, in the arterioles, to bands of fibers making up the body of the vessel in the medium sized arteries and veins.

There is elastic tissue in all but the smallest arteries, and it is also found in some veins. It varies in amount from a loose network to dense membranes. In the intima of the larger arteries the elastic tissue occurs as sheets,

which under the microscope appear perforated and pitted, the so-called fenestrated membrane of Henle.

The nutrient vessels of the arteries and veins, the vasa vasorum, are present in all the vessels except those less than one millimeter in diameter. The vasa vasorum course in the external coat and send capillaries into the media, supplying the outer portion of the coat and the externa with nutritive material. The nutrition of the intima and inner portion of the media is obtained from the blood circulating through the vessel. Lymphatics and nerves are also present in the middle and outer layers of the vessels.

Arteries.

The structure of the arteries varies notably, depending upon the size of the vessel. A cross section of the thoracic aorta reveals a dense network of elastic fibers, occupying practically all of the space between the single layer of endothelial cells and the loose elastic and connective tissue network of the outer layer. Smooth muscle fibers are seen in the middle coat, but, in comparison with the mass of elastic tissue, they appear to have only a limited function.

In a cross section of the radial artery one sees a wavy outline of intima, caused by the endothelium following the corrugations of the elastica. The endothelium is seen as a delicate line, in which a few nuclei are visible. The media is comparatively thick, and is composed of muscle cells, arranged in flat bundles, and plates of elastic tissue. Between the media and the externa the elastic tissue is somewhat condensed to form the external elastic membrane. The adventitia varies much in thickness, being better developed in the medium-sized than in the large arte-

ries. It is composed of fibrous tissue mixed with elastic fibers.

"Followed toward the capillaries, the coats of the artery gradually diminish in thickness, the endothelium resting directly upon the internal elastic membrane so long as the latter persists, and afterward on the rapidly attenuating media. The elastica becomes progressively reduced until it entirely disappears from the middle coat, which then becomes a purely muscular tunic, and, before the capillary is reached, is reduced to a single layer of muscle cells. In the precapillary arterioles the muscle no longer forms a continuous layer, but is represented by groups of fiber cells that partially wrap around the vessel, and at last are replaced by isolated elements. After the disappearance of the muscle cells the blood vessel has become a true capillary. The adventitia shares in the general reduction, and gradually diminishes in thickness until, in the smallest arteries, it consists of only a few fibroelastic strands outside the muscle cells." (Piersol's Anatomy.)

The large arteries differ from those of medium size mainly in the fact that there is no sharp line of demarcation between the intima and the media. There is also much more elastic tissue distributed in firm bundles throughout the media, and there are fewer muscle fibers, giving a more compact appearance to the artery as seen in cross section. The predominance of elastic tissue permits of great distention by the blood forced into the artery at every heartbeat, the caliber of the tube being less markedly under the control of the vasomotor nerves than is the case in the small arteries, where the muscle tissue is relatively more developed. The adventitia of the large arteries is strong and firm, and is made up of interlacing fibroelastic tissue, of which some of the bundles are arranged longitudinally.

Veins.

The walls of the veins are thinner than those of the arteries; they contain much less elastic and muscular tissue, and are, therefore, more flaccid and less contractile. Many veins, particularly those of the extremities, are provided with cup-like valves opening toward the heart. These valves, when closed, prevent the return of the blood to the periphery and distribute the static pressure of the blood column. The bulgings caused by the valves may be seen in the superficial veins of the arm and leg. There are no valves in the veins of the neck, where there is no necessity for such a protective mechanism, gravity sufficing to drain the venous blood from the cranial cavity.

Capillaries.

These are endothelial tubes in the substance of the organs, the tissue of the organ giving them the necessary support. They are the final subdivisions of the blood vessels, and the vast capillary area offers the greatest amount of resistance to the blood flow, thus serving to slow the blood stream and allowing time for nutritive substances or waste products to pass from and to the blood. Usually the capillaries are arranged in the form of a network, the channels in any one tissue being of nearly uniform size, and the closeness of the mesh depending upon the organ. Thus, in the lung the mesh work is closest; in organs of great functional activity—as in the kidneys, the thyroid, the liver, etc.—there is an enormous capillary network.

The capillaries have no nerve supply, but are flushed or emptied entirely by the dilatation or contraction of the small arteries (arterioles). The capillary resistance really depends to a great extent on the behavior of the very small

arteries, in which are a few muscle cells sufficient to close the lumen of the vessel when excessively stimulated and thus shut off a capillary area. When this happens to great numbers of the smallest arteries, parts of organs or whole organs may be rendered anemic, and, in the case of the fingers or toes, small portions may actually become gangrenous.

CHAPTER II.

PATHOLOGY.

The whole subject of the pathology of arteriosclerosis has been much enriched by the study of the experimental lesions produced by various drugs and micro-organisms upon the aortas of rabbits. Simple atheroma must not be confused with the lesions of arteriosclerosis. The small whitish or yellowish plaques so frequently seen on the aorta and its main branches, may occur at any age, and have seemingly no great significance. Such plaques may grow to the size of a dime or larger, and even become eroded. They represent fatty degeneration of the intima which, at times, has no demonstrable cause; at times follows in the course of various diseases, and undoubtedly is due to disturbances of nutrition in the intima. Except for the remote danger of clot formation on the uneven or eroded spot, these places are of no special significance, and are not to be confused with the atheroma of nodular sclerosis.

The lesions of arteriosclerosis are of a different character. It has been customary to differentiate three types: (1) nodular; (2) diffuse; (3) senile. It must be understood that this is not a classification of distinct types. As a rule in advanced arteriosclerosis, lesions representing all types and all grades are found. The nodular type, however, may occur in the aorta alone, the branches remaining free. This is most often found in syphilitic sclerosis where the lesion is confined to the ascending portion of the arch of the aorta.

The retrogressive changes of advancing years can not

be rightly termed disease, yet it becomes necessary to regard them as such, for the senile changes, as we shall see, may be but the advanced stages of true arteriosclerosis. Much depends on the nature of the arterial tissue and much on the factors at work tending to injure the tissue. A man of forty years may therefore have the calcified, pipe stem arteries of a man of eighty. Our parents determine, to great extent, the kind of tissue with which we start life. The arteries are elastic tubes capable of much stretching and abuse. In the aorta and large branches there is much elastic tissue and relatively little muscle. When the vessels have reached the organs, they are found to be structurally changed in that there is in them a relatively small amount of elastic tissue but a great deal of smooth muscle. This is a provision of nature to increase or decrease the supply of blood at any point or points.

The aorta and the large branches are distributing tubes only. It is after all in the arterioles and smaller arteries that the lesions of arteriosclerosis do the most damage. A point to be emphasized is that the whole arterial system is rarely, if ever, attacked uniformly. That is, there may be a marked degree of sclerosis in the aorta and coronary arteries with very little, if any, change in the radials. On the contrary, a few peripheral arteries only may be the seat of disease. A case in point was seen at autopsy in which the aorta in its entirety and all the large peripheral branches were absolutely smooth. In the brain, however, the arteries were tortuous, hard, and were studded with miliary aneurysms. It is not possible to judge accurately the state of the whole arterial system by the stage of the lesion in any one artery; but on the whole one may say that an undue thickening of the radial artery indicates analogous changes in the mesenteric arteries and in the aorta.

So far as the anatomical lesions in the aorta and

branches are concerned, there is much uniformity even though the etiological factors have been diverse. The only difference is one of extent. To Thoma we owe the first careful work on arteriosclerosis. He regarded the lesion in arteriosclerosis as one situated primarily in the media; there is a lack of resistance in this coat. His views are now chiefly of historical interest. As the author understands him, he considered a rupture in the media to be the cause of a local widening and consequently the blood could not be distributed evenly to the organ which was supplied by the diseased artery or arteries. Moreover, there was danger of a rupture at the weak spot unless this were strengthened. It was essential for the even distribution of blood that the lumen be restored to its former size. Nature's method of repair was a hypertrophy of the subintimal connective tissue and the formation of a nodule at that point. The thickening was compensatory, resulting in the establishment of the normal caliber of the vessel. Thoma showed that by injecting an aorta in the subject of such changes, with paraffin at a pressure of 160 mm. of mercury, these projections disappeared and the muscle bulged externally. He recognized the fact that the character of the artery changed as the years passed, and to this form he gave the name, primary arteriosclerosis. To the group of cases caused by various poisonous agents, or following high peripheral resistance and consequent high pressure, he gave the name, secondary arteriosclerosis. This is a useful but not essential division, as the changes which age and high tension produce may not be different from those produced in much younger persons by some circulating poison. And most important to bear in mind, octogenarians may have soft, elastic arteries.

As the body ages, certain changes usually take place in the arteries leading to thickening and inelasticity of their

walls. This is a normal change, and in estimating the palpable thickening of an artery, such as the radial, the age of the individual must always be considered.

Thayer and Fabyan, in an examination of the radial artery from birth to old age, found that, in general, the artery strengthens itself, as more strain is thrown upon it, by new elastica in the intima and connective tissue in the

Fig. 2.—Cross-section of a coronary artery, x50, showing nodular sclerosis. Note the heaping up of cells in the intima, the fracture of the elastica, and the destruction of the media beneath the nodule. The primary lesion evidently was in the media. The thickened intima is the effort on the part of nature to heal the breach. At such places as shown here aneurysms may form. (Microphotograph.)

media and adventitia. Up to the third decade there is only a strengthening of the media and adventitia. During the third and fourth decades there is also distinct connective tissue thickening in the intima. "In other words, the strain has begun to tell upon the vessel wall, and the yielding tube

fortifies itself by the connective tissue thickening of the intima and to a lesser extent of the media." By the fifth decade the connective tissue deposits in the intima are marked, there is an increase of fibrous tissue upon the medial side of the intima and, in lesser degree, throughout the media. "Finally, in these sclerotic vessels degenerative changes set in, which are somewhat different from those seen in the larger arteries, consisting, as they do, of local areas of coagulation necrosis with calcification, especially marked in the deep layers of the connective tissue thickenings of the intima, and in the muscle fibers of the media, particularly opposite these points. These changes may . . . go on to actual bone formation." The mesenteric artery differs in some respects from the radial, but in the main, the changes brought about by age are the same. Thayer and Fabyan note two striking points of difference: "(1) calcification is apparently much less frequent than in the radials; (2) in several cases plaques were seen with fatty softening of the deeper layers of the intima and superficial proliferation—a picture which we have never seen in the radial." (See Fig. 2.)

Aschoff's studies of the aorta show that, "in infancy the elastic laminæ of the media stand out sharply defined, well separated from each other by the muscle layers, which are well developed. . . . From childhood there is to be observed a slowly progressive increase in the elastic elements of the media. Not only do the individual lamellæ seen in cross-sections become thicker, but also they afford an increasing number of fine secondary filaments feathering off from these and crossing the muscle layer, so that now they are no longer sharply defined, but more ragged upon cross-section. This progressive increase attains its maximum at or about the age of thirty-five, and from now on for the next fifteen years the condition is relatively stationary. After fifty

there is to be observed a slowly progressive atrophy of the elastica. The media becomes obviously thinner and presumably weaker." (Adami.) It has also been found (Klotz) that after the age of thirty-five, the muscle of the media begins to exhibit fatty degeneration which after fifty years is well marked. The fatty degeneration may then give place to a calcareous infiltration or the fibers may undergo complete absorption. It would appear that the thinning of the aortic media is due not so much to the atrophy of the elastic tissue as to that of the muscle tissue. The elastic tissue does lose its specific property and the artery thus becomes practically a connective tissue tube.

Scheel has made very careful measurements of the ascending, the thoracic, and the abdominal aorta, and the pulmonary artery. He found that from birth to sixty years, the aorta became progressively wider and lost its elasticity. The pulmonary changed little, if at all, after thirty to forty years, and where before it was wider than the aorta, it now was found to be smaller. In chronic nephritis both were widened. The continuous increase of width and length of the aorta stands in reverse relationship to the elasticity of its walls.

Although the division of the lesions into nodular, diffuse, and senile has been the usual one, it is better to separate three groups into nodular, diffuse or senile, and syphilitic. There is more known about the histology of the syphilitic form and the lesions are characteristic, even a macroscopical examination sufficing in most cases for a definite diagnosis. The puckerings and scars seen on opening an aorta just above the valves and on the ascending portion of the arch are determinate.

In the nodular form the lesions are found on the aorta and large branches particularly at or near the orifices of branching vessels. These nodules may increase in size

forming rather large, slightly raised plaques of yellowish-white color. They are, as a rule, irregularly scattered

Fig. 3.—Arteriosclerosis of the thoracic and abdominal aorta, showing irregular nodules, atheromatous plaques, denudation of the intima, thin plates of bone scattered throughout with spicules extending into the lumen of the vessel. Note the contraction of the openings of the large branches, the rough appearance of the aorta and the greater degree of sclerosis of the upper two-thirds, *i. e.*, of the aorta above the diaphragm. This aorta in the recent state was much thickened and almost inelastic.

throughout the aorta and branches and tend to be more numerous and larger in the abdominal aorta. The initial

lesion is in the media, consisting of an actual dissolution of this coat with rupture of the elastic fibers and infiltration with small round cells. There is thus a weak spot in the artery. Hypertrophy of the intimal cells takes place,

Fig. 4.—Normal aorta. Compare with Fig. 3. Note the perfectly smooth, glossy appearance of the intima. The openings of all the intercostal arteries are distinctly seen. In the recent state this artery was highly elastic, capable of much stretching both transversely and longitudinally.

layer upon layer being added in an attempt to strengthen the vessel at the injured place. Coincidently with this, there is thickening by a connective tissue growth in the

adventitia. The process begins, at least in syphilis, around the terminals of the vasa vasorum. It will be recalled that the blood supply of the inner portion of the media comes from within the vessel itself. As the intimal growth increases, the blood supply is cut off. The inevitable result is softening of the portion farthest from the lumen of the vessel. As a rule there has been a sufficient growth of connective tissue in the media and adventitia to repair the damage done to the media. This softening and dissolution gives rise to a granular débris composed of degenerated cells and fat. This is the so-called atheromatous abscess. There are no leucocytes as in ordinary pus. These "abscesses" are frequent and in rupturing leave open ulcers with smooth bases, the atheromatous ulcer. A further change which often takes place is calcification of the bases of the ulcers and calcification of the softened spots before rupture takes place. This only occurs in advanced cases. (See Figs. 3 and 4.)

Rather contrary to what one would expect, there are no new capillaries advancing from the media to the intima in the nodular form of arteriosclerosis, consequently there is no granulation tissue to heal and leave scars. It must be borne in mind that these changes rarely, if ever, are the only ones found throughout the arterial system. Nevertheless, the manifold changes, as will be shown within, appear to be but stages of one primary process.

The character of the changes which are known as diffuse arteriosclerosis seems to have, at first sight, little in common with those of the nodular sclerosis. The aorta may or may not have plaques of nodular sclerosis, while the arteries, such as the radial or temporal, may be beaded or pipe stem in hardness. In spite of these far advanced peripheral lesions the aorta may appear smooth but it is markedly dilated, particularly the thoracic portion, it is

noticeably thinned even on macroscopical examination, it has elongated as evidenced by its slight tortuosity, and it has lost the greater part of its elasticity. The abdominal aorta is not so extensively affected, although this, too, shows some elongation and slight thinning. This is considered by some pathologists to be the uncomplicated form of the so-called senile arteriosclerosis. It is more of the nature of a degenerative change, it is true, but, as will be shown later, it has its beginnings, at times, in comparatively young persons and its etiology is not simple. This type has been studied most carefully by Moenckeberg, who showed that on the large branches of the aorta there were depressions due to a degeneration of the middle coat. These depressions encircled the vessel to a greater or lesser extent, causing small bulgings at such places and giving to the vessel a beaded appearance. On viewing such an artery held to the light, the sacculated spots are seen to be much thinner than the surrounding artery. Associated with such changes in the aorta and large branches is marked sclerosis of the smaller arteries. Intimal fibrosis is common, together with hypertrophy and fibrosis of the middle coat. Not infrequently periarterial thickening is also seen. Calcification of the media is found and is said to be preceded by hypertrophy of the middle coat.

Pure cases of this, the so-called Moenckeberg type, are seen but seldom. Most commonly there are nodules and plaques in the aorta and large branches together with thinning and sacculation of other portions of the vessels' walls. While the two processes appear at a glance to be so different from each other, it is possible for them to have a common origin. The initial lesion is in the media but the resulting sclerotic changes depend upon the kind of vessel, the strength of the coats, the pressure in the vessel, and other causes.

Thus the sclerosis of the radials of such an extent that these arteries are easily palpable, appears to be a different process from that of the sclerosis in the aorta, yet fundamentally it is the same. The difference lies in the anatomical structure of the two vessels, and possibly also in the degree of stretching and strain to which the vessels are subjected at every heart beat. In the radial artery the media as usual is affected first. The muscle cells undergo degeneration and either marked thickening takes place or sacculation results, depending upon the severity of the exciting cause. Calcification of the media is common. This occasionally takes the form of rings encircling the vessel, and gives to the examining finger the sensation of feeling a string of fine beads. There may be calcification of the subintimal tissue without deposits of lime salts in the media, but this is more commonly found in the larger arteries. When the calcification occurs in plates through the media, the well known pipe stem vessel is produced.

The senile sclerosis found in old people is usually a combination of the Moenckeberg type in the large and medium-sized arteries, and the nodular type in the aorta, leading eventually to calcareous intimal deposits, and widened, elongated, inelastic aorta.

The seat of election of the syphilitic poison is in the aorta just above the aortic valves, and in the ascending portion of the arch. There are semitranslucent, hyaline-like plaques which have a tendency to form into groups and, instead of undergoing an atheromatous change as in the ordinary nodular form of arteriosclerosis, they are prone to scar formation with puckering, so that macroscopically the nature of the process may, as a rule, be readily diagnosed. Microscopically the process is found to be a subacute inflammation of the media, what has been called a mesaortitis. There is marked small celled infiltration around some of

the branches of the vasa vasorum and there appears to be actual absorption of the tissue elements of the middle coat. This is accompanied by hypertrophy of the intimal tissue. There follows degeneration in the deeper portions of this new tissue and new capillaries are formed which have their origin in the inflammatory area in the media. As is everywhere the case throughout the body, granulation tissue in the process of healing contracts and forms scars. This explains the scar formation in the aorta. When the process is more acute, instead of having a reparative attempt on the part of the intima, there is actual stretching of the wall at the weakened spot and there results an aneurysmal dilatation. **Spirochetæ pallidæ** have been found in the degenerated media and in small gummata which were situated beneath the intima. Within the past year it has been found that a large percentage of patients with cardiovascular disease give the Wassermann reaction, a specific blood serum reaction in the blood of persons who have had syphilis. In cases of aortic insufficiency, the reaction is present in almost every case. This is in marked contrast to the cases of diffuse endocarditis where the reaction is rarely present.

According to Adami the effects of syphilis upon the aorta are the following: (1) the primary disturbance is a granulomatous, inflammatory degeneration of the media; (2) this leads to a local giving away of the aorta; (3) if this be moderate it results in a strain hypertrophy of the intima and of the adventitia, with the development of a nodose intimal sclerosis; (4) if it be extreme, there results, on the contrary, an overstrain atrophy of the intima and aneurysm formation; (5) the intimal nodosities are here not of an inflammatory type and are non-vascular, although, with the progressive laying down of layer upon layer of connective tissue on the more intimal aspect of the intima, the earlier and deeper-placed layers of new tissue gain less and less

nourishment, and so are liable to exhibit fatty degeneration and necrosis; (6) these products of necrosis exert a chemotactic influence upon the nearby vessels of the medial granulation tissue, with, as a result, (a) a secondary and late entrance of new vessels into the early and deeply-placed atheromatous area, (b) absorption of the necrotic products, (c) replacement by granulation tissue, (d) contraction of the granulation tissue, and (e) depression and scarring of the sclerotic nodules so characteristic of syphilitic sclerosis.

In the smaller arteries and arterioles the arteriosclerotic process appears on superficial examination to be a different process from that in the aorta and large arteries, but the difference is only apparent. It will be recalled that there is relatively much more muscle tissue in the arterioles than in the large arteries. The size, of course, is much less. Large nodular plaques are not possible. The atheromatous degeneration is not marked. In the smaller muscular arteries is seen the intimal proliferation, the stretching of the Moenckeberg type, and the calcification of the media rather than the intima. The media is thinned beneath the marked intimal proliferation so that the artery exhibits translucent areas when held to the light. Again, there is seen degeneration of the muscle and replacement by connective tissue with or without hypertrophy of the intima. In the arterioles three kinds of changes occur: a muscular hypertrophy; a fibrosis of all the coats; or a marked proliferation of the intimal endothelium. The last two are probably the same process, the connective tissue having its origin in the proliferated endothelial cells. Such a deposition of layer upon layer of cells in an arteriole and the resulting fibrosis leads to the condition of disappearance of the lumen of the vessel, endarteritis obliterans. This obliterating endarteritis is not, of course, due alone to syphilis. Syphilis is only a type of poison which produces

such changes as have been described above. It is in the organs such as the kidney, liver, spleen, and intestines that one sees the most perfect examples of this obliterating endarteritis. Endarteritis deformans is a term applied to the condition of the arteries as a result of irregular thickenings and deposits of lime salts in the walls. These changes give rise to marked tortuosity of the vessels.

Occasionally such an obliterating process takes place in a larger artery. A thrombus forms and by a process of central softening, new channels permeate the thrombus, thus restoring to some extent the function of the vessel.

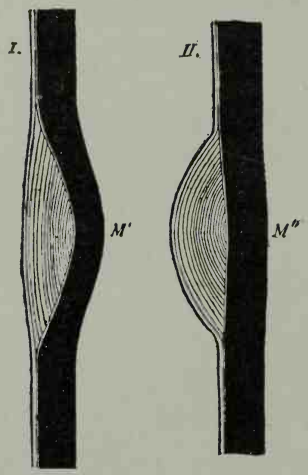

Fig. 5.—I, media weakened at M′ with overgrowth of intima filling in the depression. II, with postmortem rigor and contraction of the muscles of the media and removal of the blood pressure from within, the stretched media at M″ contracts; the intimal thickening thus projects into the arterial lumen. (After Adami.)

That the same process leads at one time to thinning and at another time to thickening of the arterial walls has been noted above. Prof. Adami holds that the regular development of layer upon layer of new connective tissue is non-inflammatory. He calls it a "strain hypertrophy." It is analogous to the localized hypertrophy of bone where the muscle tendons are attached, as is so frequently seen in

athletes. The increased tension on connective tissue, provided that it is not overstrained, leads to its overgrowth but only when there is sufficient nourishment. Such conditions are adequately fulfilled in the arteries. When a local giving way under pressure occurs in the media, the intima is put on the stretch (see Fig. 5), and there results a hypertrophy of the intima until the volume of the new tissue and the resistance which this affords to the mean distending force, balances the loss sustained by the weakened media. When the balance is struck, the hypertrophy is arrested. The youngest tissue is thus found directly beneath the endothelium. Now should this local weakening of the media have an acute origin, instead of a stimulus to growth there is overstrain, and there is, in consequence, not hypertrophy but atrophy. The beginning process is here a mesaortitis, but the acuteness of the poison, and the pressure from within the artery so stretches the artery that there is no compensatory hypertrophy, but a thinning, and the ground is prepared for aneurysmal dilatation or pouching.

Again, one not infrequently encounters intimal nodosities when the underlying media appears of normal thickness. The explanation of this apparent exception is that the media in the living aorta is actually thinned, but the layers of subintimal tissue deposited over the weak spot due to strain hypertrophy become bulged inward when the pressure is relieved, as at post mortem. The media has not lost all of its elasticity (see Fig. 6), hence it contracts and there is the appearance of a nodule on the intima beneath which is a media equal in thickness to that of the healthy surrounding media.

The essential lesion in arteriosclerosis of the aorta and large arteries is a degeneration in the middle coat. This may be brought about by a variety of poisons circulating in the body. In syphilis, for example, the initial lesion has

been shown to be a mesaortitis. The media seems to be dissolved, the artery is consequently thinned, there is actual depression along the level of the vessel. The elastic fibers disappear and small celled infiltration takes its place. The

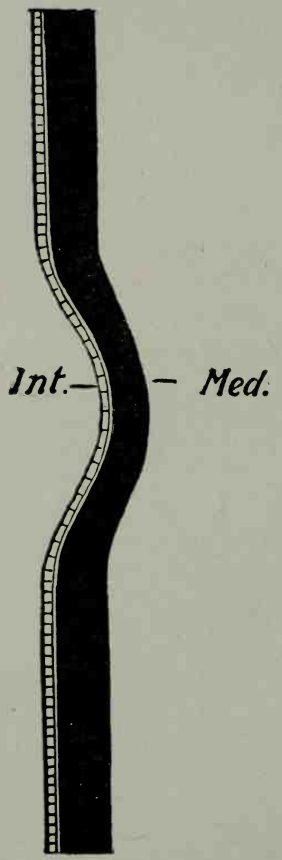

Fig. 6.—Schematic representation of the increased strain brought to bear upon the cells of the intima, Int., when the media, Med., undergoes a localized expansion through relative weakness. (After Adami.)

intima hypertrophies, layer upon layer being added in an attempt to restore the strength of the vessel. There is also, as a rule, rather pronounced hypertrophy of the adventitia.

The lesions produced experimentally in animals, par-

ticularly in rabbits, have added confirmation to the views above expressed. They have also given us, in a way, information as to the early lesions of arteriosclerosis in the arteries of man.[1] Following the injection of small, repeated doses of adrenalin over a certain period of time, changes occur in the arteries of rabbits which are arteriosclerotic in type, the essential lesion being a degeneration of the muscular and elastic tissue of the media with the consequent production of aneurysm in the vessel. This is quite like the type of arteriosclerosis in man which has been so well described by Moenckeberg. The degenerations in the arteries following the experimental lesions are of the nature of a fatty metamorphosis, and later proceed to calcification. Barium chloride, digitalin, physostigmin, nicotine and other substances, as well as adrenalin, have been found to exert a selective toxic action on the muscle cells of the middle coat of the aorta. The infundibular portion of the pituitary body, the portion which is developed from the infundibulum of the brain, possesses an internal secretion, which, injected intravenously, causes a marked rise of blood pressure and slowing of the heart beat. So far as I know, this active principle of the gland has not been used in an attempt to produce experimentally the lesions of arteriosclerosis.

The most frequent site of disease in these experimental lesions is the thoracic aorta, and it is there also that the most severe changes are seen. While the toxic action is felt in the vessels all over the body, the lesions are, as a rule, scattered and small. The thoracic aorta stands the brunt of the high pressure, and this combined with the poisonous action of the drug or drugs, results in the formation of a fusiform aneurysmal dilatation which stops at the diaphragmatic opening. The aortic opening in the diaphragm

[1] For an excellent summary of experimental arterial disease see Adler, I.: Present Status of Experimental Arterial Disease. Am. Jour. Med. Sc., 1908, cxxxvi, p. 241.

seems to act as a flood gate, allowing only a certain amount of blood to flow through, and thus the abdominal aorta is protected to a great extent from the deleterious effects of increased pressure. Focal degenerative lesions are, however, found in the abdominal aorta.

Changes somewhat analogous to those found in the human aorta as the result of intimal proliferations, are produced in animals by the toxins of the typhoid bacillus and the Streptococcus pyogenes. Clinically, Thayer and Brush have found that the arteries of those who have recovered from an attack of typhoid fever are more palpable than the arteries of average individuals of equal age who have never had the disease.

Experimentally, the changes caused by the toxins above noted are proliferations of cells in the intima and subintimal tissues, and a breaking up of the internal elastic laminæ into several parallel layers which stretch themselves among the proliferating cells. The diphtheria toxin, on the contrary, produces a lesion more like that caused by adrenalin. All pathologists are not agreed as to whether the experimental lesions produced by blood pressure raising drugs are similar to the arteriosclerotic changes in the arteries of man.

Some of the work on rabbits has been discredited for the reason that arteriosclerosis appears spontaneously in about fifteen per cent of all laboratory rabbits. Furthermore, comparatively young rabbits have been found with arteriosclerosis. The spontaneous lesions cannot be distinguished histologically from those due to adrenalin. They differ macroscopically in that the lesion is usually limited to a few foci near the origin of the aorta.[1]

Lesions produced by the drugs enumerated above represent one type of experimental arteriosclerosis. More in-

[1] Hill, M. C.: Arch. Int. Med., 1910, v, p. 22.

teresting and important are the experiments showing that high tension alone is capable of producing lesions in arteries which in all respects correspond to Adami's strain hypertrophy and overstrain theory. It has been shown [1] that when a portion of vein is placed under conditions of high arterial pressure, as in a transplantation of a portion of vein into a carotid artery, the vein undergoes marked connective tissue hypertrophy which includes all the coats. This is evidently strain hypertrophy. Again, it has been demonstrated [2] that by suspending a previously healthy rabbit by the hind legs for three minutes daily over a period of three to four months, there results hypertrophy of the heart with thinning and dilatation of the arch and the upper part of the thoracic aorta. No change was found in the abdominal aorta. The carotids, however, were larger than normal and they showed typical intimal sclerosis with connective tissue thickening. Thus, the two processes occurred due to the same cause—hypertension. First, a dilatation and thinning of arterial walls; second, a thickening and intimal hypertrophy of other near-by arterial walls. The difference in effect appears to lie in the structure of the vessels themselves and in the extent of strain put upon them. If the strain is pronounced, there is dilatation; if only moderate, there is thickening of the walls. These two changes, the arterial thinning (Moenckeberg type) and intimal thickening of ordinary (senile) arteriosclerosis, therefore appear to be diverse manifestations of a common causative agent.

The changes in the intima constitute the effort on the part of nature to repair a defect in the vessel wall which is to compensate for the weakened media and the widened lumen. This applies only to true arteriosclerosis, not to

[1] Carrel: Jour. Exper. Med., 1908, x, p. 130.
[2] Klotz, O.: Quoted by Adami, loc. cit.

the condition produced experimentally by the toxin of the typhoid bacillus, for example.

When an artery loses its elasticity and begins to have connective tissue deposited in its walls, the pressure of the blood stretches the vessel which is now no longer capable of retracting when the pulse wave has passed, and, in consequence, the artery is actually lengthened. This necessarily causes a tortuosity of the vessel which can be easily seen in such arteries as the temporals, brachials, radials, and other arteries near the surface of the skin.

The exact mechanism of increase of blood pressure is not satisfactorily explained. With the exception of the vessels in the brain and the lungs,[1] the smaller arteries all over the body are supplied with vasoconstrictor and vasodilator nerve fibers from the sympathetic nervous system. Normally when an organ is actively functionating the vessels are widely dilated and the flow of blood is rapid. Among the many factors which influence blood pressure and blood supply must be reckoned the psychic.

We know that normally there is a certain resistance offered to the propulsion of blood through the arteries by the contraction of the heart. This tonus is essential to the maintenance of an equalized circulation. The muscular arterioles throughout the body by their tonus serve to keep up the normal blood pressure and to distribute the blood evenly to the various organs. Contraction of a large area of arterioles increases the blood pressure and, strangely enough, the arteries respond to increased arterial pressure, not by dilatation, but by contraction. It would appear that rise of blood pressure tends to throw increased work upon the musculature of the arterioles. This may be sufficient only to cause them to hypertrophy, but further strain may

[1] Probably there are vasomotor fibers to the blood vessels of the lungs. See article by H. T. Karsner, Nerve Fibrillae in the Pulmonary Artery of the Dog. Jour. Exper. Med., 1911, XIV, 322.

easily lead to exhaustion and to dilatation. "As a result strain hypertrophy of the intima shows itself with thickening, and it may also be of the adventitia, resulting in chronic periarteritis. And now with continued degeneration of the medial muscle in those muscular arteries, fibrosis of the media may also show itself. I would thus regard muscular hypertrophy of the arteries and fibrosis of the different coats as different stages in one and the same process. Whether these peripheral changes are the more marked, or the central, depends upon the relative resisting power of the elastic and muscular arteries of the individual respectively." (Adami.)

It is conceivable that in one section of the body the vessels may be markedly contracted, but if there is dilatation in some other part there will be no increased work on the part of the heart, and theoretically, there should be no rise of blood pressure. The vascular system, however, while likened to a system of rubber tubes, must be regarded as a very live system, every subsystem having the property of separate control.

For blood tension to be raised all over the body, conditions must favor the generalized contraction of a large area of arterioles. Some authors consider that the so-called viscosity of the blood also is a factor in the causation of increased tension. The usual cause for the high tension is the presence in the blood of some poisonous substance.

It must be borne in mind that the great splanchnic area is capable of holding all the blood in the body and in respect of its liability to arteriosclerosis, it is second only to the aorta and coronary arteries. The enormous area of the skin vessels could probably contain most of the blood. The tone of the vasoconstrictor center controls the distribution of blood throughout the body. The fact that the vessels in the splanchnic area are frequently attacked by

sclerotic changes means, as a rule, increase of work for the heart. The resistance offered to the passage of the blood signifies that, for blood to travel at the same rate that it did before the resistance set in, more power must be expended in its propulsion. In other words, the heart must gradually become accustomed to the changed conditions, and, as a result of increased work, the muscle hypertrophies. (See Fig. 7.)

In diffuse arteriosclerosis the heart is always hypertrophied. This is a result, not a cause of the condition. In the pure type, there is hypertrophy only of the left ventricle without dilatation of the chamber. The muscle fibers are increased in number and in size, and there are frequently areas of fibrous myocarditis due to necrosis caused by insufficient nutrition of parts of the muscle. In these cases the coronary arteries share in the generalized arteriosclerotic process. The openings of the arteries behind the semilunar valves may be very small. There is often thickening and puckering of the aortic valves and of the anterior leaflet of the mitral valve leading, at times, to actual insufficiency of the orifice. Later, when the heart begins to weaken, there is dilatation of the chambers and loud murmurs result, caused by the inability of the nondistensible valves to close the dilated orifices. Until the compensation is established, it is impossible to say whether or not true insufficiency is present.

In senile arteriosclerosis there is the physiological atrophy of the media to be reckoned with. This change has already been referred to. When such degeneration has taken place, the normal blood pressure may be sufficient to cause stretching of the already weakened media with or without hypertrophy of the intima. The arteries may be so lined with deposits of calcareous matter that they appear as pipe stems. More frequently there are rings of

calcified material placed closely together or irregular beading, giving to the palpating finger the impression of feeling a string of very fine beads. The arteries are often tortuous, hard, and are absolutely non-distensible. At times no pulse wave can be felt.

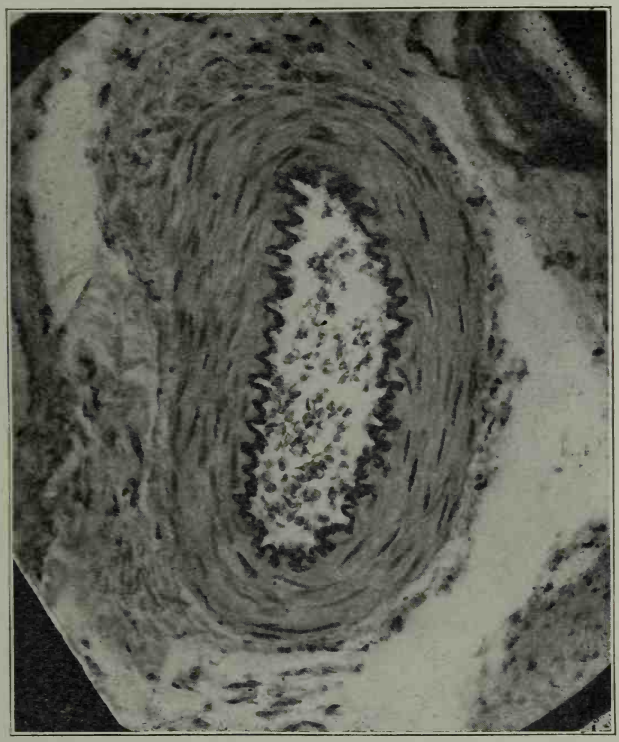

Fig. 7.—Cross-section of a small artery in the mesentery. Note that the vessel appears capable of being much widened. The internal elastic lamina is thrown into folds somewhat resembling the convolutions of the brain. Note also that the middle coat of the artery is composed almost entirely of muscle. The enormous number of such vessels in the mesentery and intestines explains the ability of the splanchnic area to accommodate the greater part of the blood in the body. Universal constriction of these vessels would naturally render the intestines anemic. The vasomotor control of these vessels plays an important role in the distribution of the blood. Small arteries in the skin and in other organs, except the brain, have a similar function. (Microphotograph, highly magnified.)

The larger arteries such as the brachials and femorals are most affected. The walls become thinned and show cracks, and areas apparently, but not actually denuded of

intima. Yellowish-white irregular, raised plaques are scattered here and there. Interspersed among these areas are irregularly shaped clean cut ulcers having as a rule a smooth base, and frequently on the base is a thin plate of calcified matter. The color of these denuded areas is usually brownish red or reddish brown. White thrombi may be deposited on these areas. The danger of an embolus plugging one of the smaller arteries is great and probably happens more often than we think. The collateral circula-

Fig. 8.—Enormous hypertrophy of left ventricle due to prolonged increased peripheral resistance. Note that the whole anterior surface of the heart is occupied by the left ventricle. The right ventricle does not appear to be much affected. A case of chronic nephritis with high blood pressure. x2/3.

tion is able to supply the thrombosed area. Should the thrombus be on the carotid arteries, hemiplegia may result from cerebral embolism. On microscopical examination of the arteries there is seen extreme degeneration of all the coats, the degeneration of the media leading almost to an obliteration of that coat. On seeing such arteries as these one wonders how the circulation could have been main-

tained and the organs nourished. Senile atrophy of the internal organs naturally goes hand in hand with such arterial changes.

There is, as a rule, no increase in arterial tension; on the contrary, the pressure is apt to be low. This is readily understood when the heart is seen. This organ is small, the muscle is much thinned, it is flabby and of a brownish tint, the so-called "brown atrophy." Microscopically, there is seen to be much fragmentation of the fibers with a marked increase of the brown pigment granules which surround the cell nuclei. Cases are seen, however, in which blood pressure increases as the patient grows older. The hearts in such cases are more or less hypertrophied and show extensive areas of fibroid myocarditis. (Fig. 8.)

From what has been said, it follows that hypertension alone may be the cause of arteriosclerosis; that certain poisons in the blood which attack the media and cause it to degenerate and weaken cause arteriosclerosis without increased blood pressure; that the normal blood pressure may be, for the artery which is physiologically weakened in an individual over fifty, really hypertension and arteriosclerosis may result. Our observations lead us to believe that the process is at bottom one and the same. The different types noted clinically depend upon the nature of the etiologic factors and the kind of arterial tissue with which the individual is endowed. This view at least brings some order out of previous chaos, and corresponds well with our present knowledge of the disease.

There are many cases of arteriosclerosis which lead to definite interference with the closure of the valves of the heart, particularly the aortic and the mitral. It has been said that puckerings of the valves frequently occur. This arteriosclerotic endocarditis at times leads to very definite heart lesions, chiefly aortic or mitral insufficiency, or both,

with, at times, murmurs of a stenotic character at the base. There is rarely true aortic stenosis, however. The murmur is caused by the passage of the blood over the roughened valves and into the dilated aorta. Aortic stenosis is one of the rarest of the valvular lesions affecting the valves of

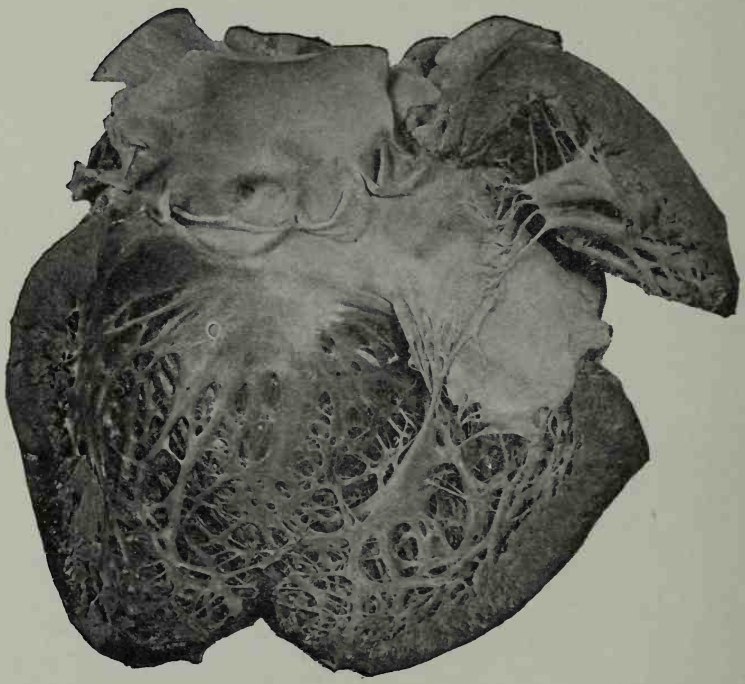

Fig. 9.—Aortic incompetence with hypertrophy and dilatation of left ventricle, the result of arteriosclerosis affecting the aortic valves. Note how the valves have been curled, thickened, and shortened, the edges of valves being a half inch below the upper points of attachment. The anterior coronary artery is shown, the lumen narrowed. (Reduced one-half.)

the left heart, and should be diagnosed only when all factors, including the typical pulse tracings, are taken into consideration. (Fig. 9.)

The kidneys, as a rule, show extensive sclerosis. They are small, firm, and contracted and not always to be differentiated from the contracted kidneys of chronic inflammation. The lesions of the arteriosclerotic kidney are due

to narrowing and eventual obstruction of the afferent vessels. The organs are usually bright red or grayish red in color. At times there is marked fatty degeneration of cortex and medulla, giving to them a yellowish streaking. The capsule is here and there adherent, the cortex is much thinned and irregular. The surface presents a roughly granular appearance. The glomeruli stand out as whitish dots and the sclerosed arteries are easily recognized, as their walls are much thickened. The process does not, as a rule, affect the whole kidney equally, but rather affects those portions corresponding to the interlobular arteries. The replacement of the normal kidney tissue by connective tissue and the resulting contraction of this latter tissue leads to the formation of scars. As the process is not regular, the scarring is deeper in some places than in others, with the result that localized rather sharply depressed areas appear on the surface. The pelvis is relatively large and is filled with fat. The renal artery is often markedly sclerosed and the whole process may be due to localized thickening of the artery, or as part of a general arteriosclerosis. The latter is the more frequent. Microscopically, it is seen that the tubules are atrophied, the Bowman's capsules are, as a rule, thickened, and the glomeruli are shrunken or have been replaced by fibrous tissue. In places they have fallen out of the section. There is marked proliferation of connective tissue in cortex and medulla. The arterioles are thickened, the sclerosis being either of the intima or media or of both. There is even occlusion of many arterioles.

Changes in other organs as the result of arteriosclerosis of their afferent vessels occur, but are not so characteristic as in the kidney. In the brain the result of gradual thickening of the arterioles is a diminished blood supply, softening of the portion supplied by the artery, and later a

connective tissue deposit. The occurrence of thrombi is favored and, now and again, a thrombus plugs an artery which supplies an important and even vital part of the brain. The arteries of the brain are end arteries, hence there is no chance for collateral circulation. It is therefore evident how serious a result may follow the disturbance in or actual deprivation of blood supply to any of the brain centers or to the internal capsule.

Arteriosclerosis of the Pulmonary Arteries.

There have been a number of cases of sclerosis of the pulmonary arteries, either alone, or associated with general systemic arteriosclerosis. The cases thus far described have revealed wide-spread thickening of the pulmonary arteries. If one may judge by the description of the pathological changes, the condition is quite similar to that produced in a vein by transplantation along the course of an artery. Only the diffuse form with connective tissue thickening of all coats has been described. There is also obliterating endarteritis of the smaller vessels. In the etiology of the condition severe infection seems to play a prominent rôle. The constant presence of right ventricular hypertrophy is interesting, the heart dullness extends, as a rule, far to the right of the sternum. In some of the cases no demonstrable changes were observed in the bronchial arteries or in the pulmonary veins.

Sclerosis of the Veins.

Phlebosclerosis not infrequently occurs with arteriosclerosis. It is seen in those cases characterized by high blood pressure. Such increased pressure in the veins is due, for example, to cirrhosis of the liver which affects the portal

circulation, or to mitral stenosis which affects the pulmonary veins. The affected vessels are usually dilated. The intima shows compensatory thickening especially where the media is thinned. As a rule all the coats are involved in the connective tissue thickening. Occasionally hyaline degeneration or calcification of the new-formed tissue is seen. "Without existing arteriosclerosis the peripheral veins may be sclerotic usually in conditions of debility, but not infrequently in young persons." (Osler.)

In many cases of arteriosclerosis, the pathological changes are not confined to the arteries but are found in the veins as well as in the capillaries. Such cases could be called angiosclerosis.

For further details the reader is referred to articles by R. M. Pearce, by Pearce and E. McD. Stanton, and by O. Klotz which are published in the Jour. Exper. Med. between the years 1905 and 1909. CHAPTER III.

PHYSIOLOGY OF THE CIRCULATION.[1]

"The heart and the blood vessels form a closed vascular system, containing a certain amount of blood. This blood is kept in endless circulation mainly by the force of the muscular contractions of the heart; but the bed through which it flows varies greatly in width at different parts of the circuit, and the resistance offered to the moving blood is very much greater in the capillaries than in the large vessels. It follows, from the irregularities in size of the channels through which it flows, that the blood stream is not uniform in character throughout the entire circuit—indeed, just the opposite is true. From point to point in the branching system of vessels the blood varies in regard to its velocity, its head of pressure, etc. These variations are connected in part with the fixed structure of the system and in part are dependent upon the changing properties of the living matter of which the system is composed." (W. H. Howell.)

If the vascular system were composed of a central pump, projecting at every stroke a given amount of liquid into a series of rigid tubes, the aggregate cross sections of which were equal to the cross section of the main pipe, then the velocity at the openings would be the same as at the source

[1] Within the past few years a great mass of work has been done on the physiology of the circulation. The literature is voluminous—parts of it are highly technical and the actual practical value of much of the work is still *sub judice;* therefore it is not proposed in this chapter to enter into any details, as it would carry us far afield and serve no purpose in this particular volume. At the end of the book are a few references. Those who care to pursue the subject may find in the articles there enumerated details and further bibliographies.

(making allowances for friction). The problem would then be a simple one. In the circulation of the blood no such simple condition obtains. The capillary bed is an enormous area through which the blood flows slowly. From the time the blood is thrown into the aorta the velocity begins to diminish until it reaches its minimum in the capillaries. In no two persons is the initial velocity at the heart the same, nor in the same person is it the same at all times of day. The size of the heart, the actual strength of the muscle, the amount of blood ejected at every beat, and the size and elasticity of the aorta are some of the factors which determine the velocity of blood at the aortic orifice. When to these factors are added the differences in arterial tissue, the activity or resting stage of the various organs, etc., the question becomes exceedingly complicated. In spite of these many disturbing elements, attempts more or less successful have been made to estimate the velocity of the blood in animals. Thus, in the carotid of the horse the velocity was found to be 300 mm. per second (Volkman) and 297 mm. (Chauveau); in the carotid of the dog, 260 mm. (Vierordt). In the jugular vein of the dog Vierordt found the velocity to be 225 mm. per second. These figures do not represent the actual velocity of the blood in all horses or all dogs, but they do give us some general idea of the rate of flow of the blood. For man it has been calculated that the velocity in the aorta is about 320 mm. per second. The velocity is not uniform in the large arteries, where at every heart beat there is a sudden increase followed by a decrease as the heart goes into diastole. The farther away from the heart the measurements are made the more even is the flow. In the capillaries it is quite steady, as any one can prove by direct microscopical examination of the web of the frog's foot or the cat's mesentery. The rate in the capillaries of man is estimated to be between 0.5 mm. and

0.9 mm. per second. As the blood is collected into the veins and the bed becomes smaller, the velocity increases until at the heart it is almost the same as in the aorta. That the velocity could not be exactly the same is evident from the fact that the cross section of the veins, which return the blood to the right auricle, is greater than is the cross section of the aorta.

The volume of the bed is subject to rapid and wide fluctuations, which are dependent on many causes, both physiological and pathological. The call of an actively functionating organ or group of organs causes a widening of a more or less extensive area, and the velocity necessarily varies. In states of great relaxation of the vessels there may be a capillary pulse. In order to force blood at the same rate through dilated vessels as through normal vessels, there must be more blood or there must be a more rapid contraction of the central pump. What actually happens, as a rule, is an increase in the rate of the heart beat. There are conditions—such, for example, as aortic insufficiency—where actually more blood is thrown into the circulation at every beat, so that the rate is not changed.

It has been calculated that the average amount of blood thrown into the aorta at every systole of the heart is from 50 to 100 cc. This is forcibly ejected into a vessel already filled (apparently) with blood. In order to accommodate this sudden accession of fluid, the aorta must expand. The aortic valves close, and during diastole the blood is forced through the vascular system by the forcible steady contraction of the highly elastic aorta. Other large vessels which branch from the aorta also have a part in this steady propulsion of blood. From seventy to eighty times a minute the aorta is normally forcibly expanded to accommodate the charge of the ventricle. It is not difficult to under-

stand the great frequency of patches of sclerosis in the arch when these facts are borne in mind.

What relationship the viscosity of the blood has to the rate and volume of flow is not fully understood. As yet there is not much known about the subject, and no one has devised a satisfactory means of measuring the viscosity. It is thought by some that an increased viscosity assists in producing an increased amount of work for the heart.[1]

Blood Pressure.

By blood pressure is meant the force which the contraction of the left ventricle of the heart exerts in propelling onward the column of blood. In animals this has been measured directly by allowing the blood to rise in a tube placed perpendicularly to the aorta or carotid artery. This is a crude method, and has been abandoned for the more accurate and more easily measured method of forcing mercury in a U tube to record the height of the ventricular pressure in millimeters of mercury and the fluctuations due to the ventricular contraction. In man the blood pressure is most conveniently measured in the brachial artery.

Blood Pressure Instruments.

There are several instruments which are in common use for the purpose of recording blood pressure in man.

Historically, the determination of blood pressure for man began with the attempt of K. Vierordt in 1855 to measure the blood pressure by placing weights on the radial pulse until this was obliterated. The first useful instrument, however, was devised by Marey in 1876. He placed the hand in a closed vessel containing water connected by tub-

[1] For a good résumé see Krone, Deutsche Medizinische Wochenschrift, 1910, Vol. 36, p. 1438.

ing with a bottle for raising the pressure and by another tube with a tambour and lever for recording the size of the pulse waves. He maintained that when pressure on the hand was made, the point where oscillations of the lever ceased was the maximal pressure, the point where the oscillations of the recording lever was largest, was the minimal pressure.

This pioneer work was practically forgotten for twenty-five years. It was not until 1887 that V. Basch devised an instrument which was used to some extent. This instrument recorded only maximum pressure. It consisted of a small rubber bulb filled with water communicating with a mercury manometer. The bulb was pressed on the radial artery until the pulse below it was obliterated and the pressure then read off on the column of mercury. V. Basch later substituted a spring manometer for the mercury column. Potain modified the apparatus by using air in the bulb with an aneroid barometer for recording the pressure. These instruments are necessarily grossly inaccurate. Moreover, they do not record the diastolic pressure.

In 1896 and 1897 further attempts were made to record blood pressure by the introduction of a flat rubber bag encased in some non-yielding material, which was placed around the upper arm. Riva-Rocci used silk, while Hill and Barnard used leather. The latter used a bulb or Davidson syringe to force air into the cuff around the arm and palpated the radial artery at the wrist, noting the point of return of the pulse after compression of the upper arm, and reading the pressure on a column of mercury in a tube.

Except that the width of the cuff has been increased from 5 cm. to 12 cm., this is the general principle upon which all the blood pressure instruments now in use are based. Most of the apparatuses make use of a column of mercury in a U tube to record the millimeters of pressure. As the

mercury is depressed in one arm to the same extent as it is raised in the other arm the scale where readings are made is .5 cm. and the divisions represent 2 mm. of mercury but are actually 1 mm. apart.

The cuff was made 12 cm. in diameter because it was shown (V. Recklinghausen) that with narrow cuffs much pressure was dissipated in squeezing the tissues. Janeway has recently shown that with the use of the 12 cm. cuff accurate values are obtained independently of the amount of muscle and fat around the brachial artery. In other words if an actual systolic blood pressure of 140 mm. is present in two individuals, the one with a thin arm, the other with a thick arm, the instrument will record these pressures the same where a 12 cm. arm band is used. We need have no fear of obtaining too high a reading when we are taking pressure in a stout or very muscular individual. Janeway also was the first to call attention to the fact that the diastolic or minimal pressure was at the point where the greatest oscillation of the mercury took place. This is difficult to estimate in many cases as the eye can not follow slight changes in the oscillation when the pressure in the cuff is gradually reduced. Practically this is the case in small pulses.

Strassberger attempted to find the minimal pressure by palpating the radial artery when the pressure was reduced gradually. The maximum wave felt measured the diastolic pressure. Hirschfelder thinks this is a fairly accurate method provided one palpates with the ball of the finger pressing the tip against the radius, thus ensuring firm and even pressure on the artery. At best this is difficult except to those with large experience.

The Riva-Rocci instrument was modified by Cook. (See Fig. 10.) He used a glass bulb containing mercury into which a glass tube projected. The bulb was connected by

outlet and tubing to the cuff and syringe. The glass tube was marked off in centimeters and millimeters and for convenience was jointed half way in its length. The instrument could be carried in a box of convenient size. This instrument is fragile and more cumbersome, although

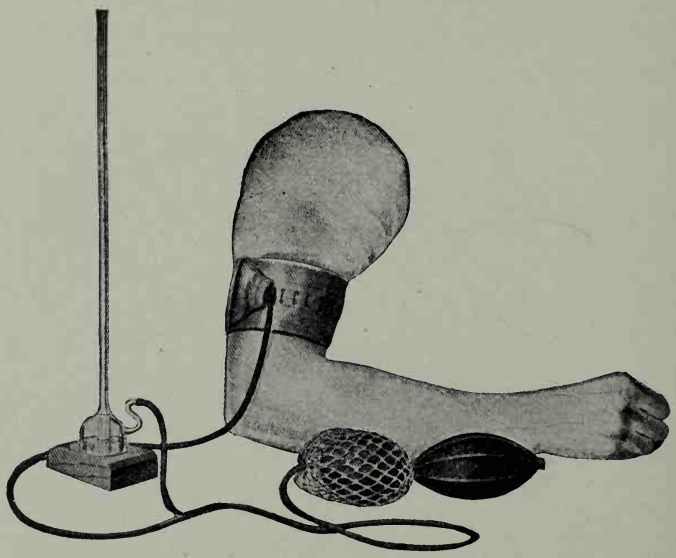

Fig. 10.—Cook's modification of Riva-Rocci's blood pressure instrument.

lighter in weight, than others and is very little used at present.

Stanton's instrument (Fig. 11) is practically Cook's made more rigid in every way but without the jointed tube. The cuff has a leather casing, the pressure bulb is of heavy rubber, the glass tube in which the mercury rises is fixed against a piece of flat metal and there are stop cocks in a metal chamber introduced between the bulb and mercury with which to regulate the in- and out-flow of air. The pressure can be gradually lowered conveniently without removing the pressure bulb.

The most accurate mercury manometer is that of Er-

langer. (Fig. 12.) The instrument is bulky and is not practicable for the physician in practice. The principle is that used by Riva-Rocci. There is an extra T-tube introduced between the manometer and air bulb connecting with a rubber bulb in a glass chamber. The oscillations of this

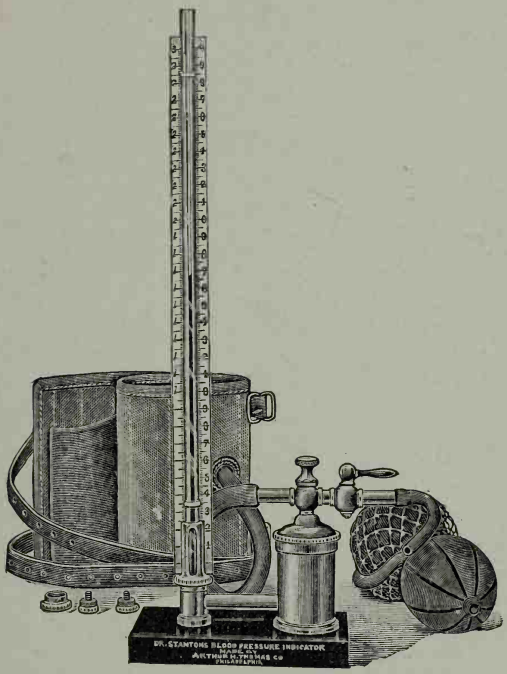

Fig. 11.—Stanton's sphygmomanometer.

are communicated to a Marey tambour and recorded on smoked paper revolving on a drum. There is a complicated valve which enables the operator to reduce the pressure with varying degrees of slowness. The mercury is placed in a U tube with a scale alongside of it. The instrument is expensive and not as easy to manipulate as its advocates would have us believe. Hirschfelder has added to the usefulness (as well as to the complexity) of the Erlanger instrument, by placing two recording tambours for

the simultaneous registering of the carotid and venous pulses. In spite of its complexity and necessary bulkiness, very valuable data are obtained concerning the auricular contractions.

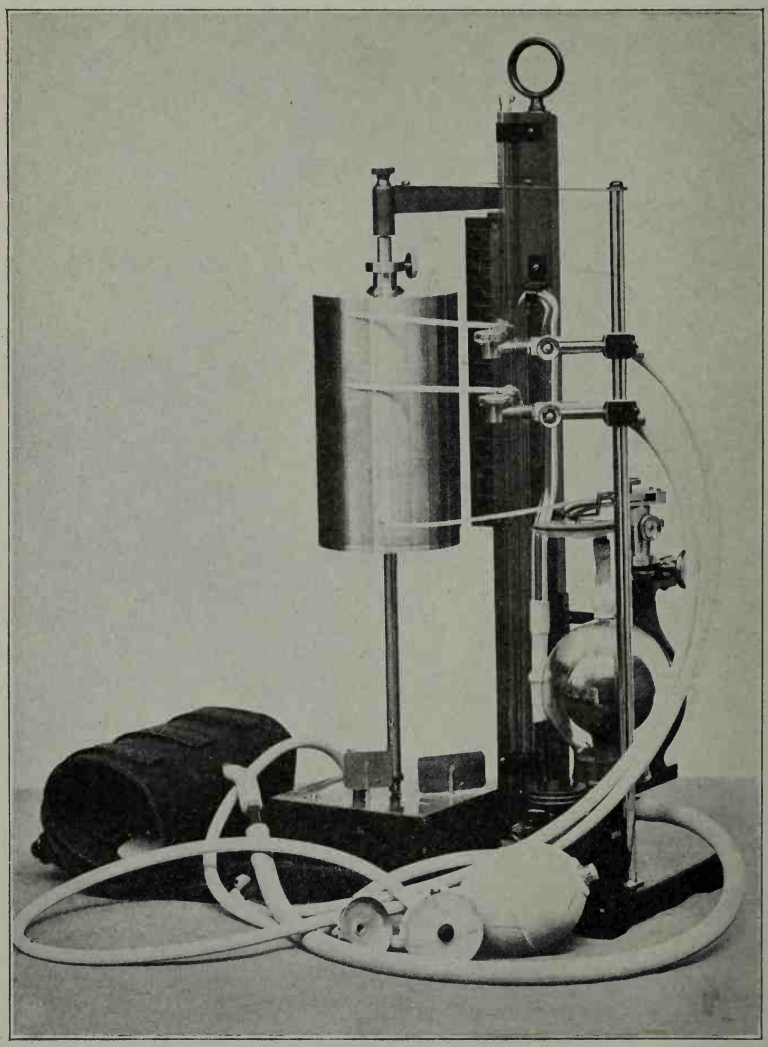

Fig. 12.—The Erlanger sphygmomanometer with the Hirschfelder attachments by means of which simultaneous tracings can be obtained from the brachial, carotid, and venous pulses.

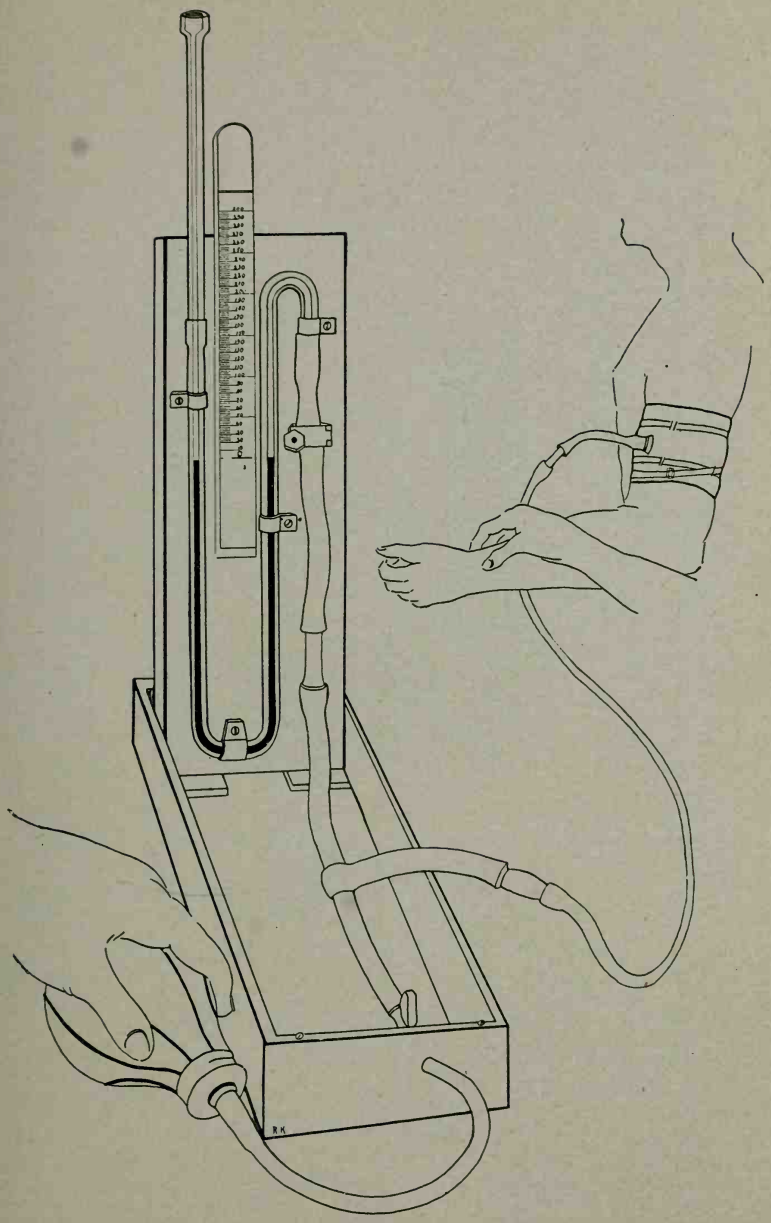

Fig. 13.—The Janeway sphygmomanometer which has been found a convenient and practicable instrument. The scale can be pushed below the level of the top of the box, the long arm of the mercury tube is disjointed and placed in the bottom of the box, the lid is then closed, and the instrument takes up but little space in the physician's bag.

A convenient instrument is the Janeway sphygmomanometer. (Fig. 13.) This is also a mercury recording instrument which is portable and accurate. I have found it very satisfactory.

The Faught instrument (Fig. 14) is larger than the Janeway but is less easily broken and is not too cumbersome to carry around. The substitution of a metal air pump for the rubber makes the apparatus more durable.

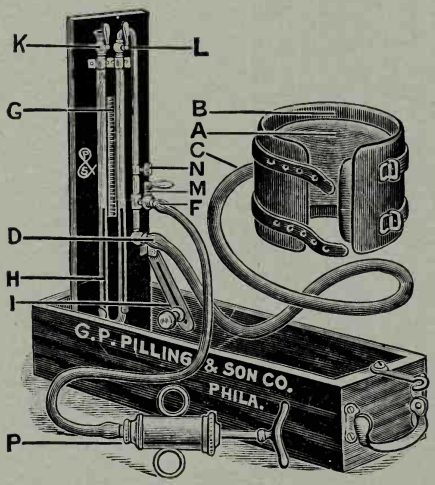

Fig. 14.—The Faught blood pressure instrument. An excellent instrument which is quite easily carried about and is not easily broken.

The V. Recklinghausen instrument is not employed to any extent in this country. It is both expensive and cumbersome and has no advantages over the other instruments.

Several other instruments have been devised and new ones are constantly being added to the already large list. With those employing mercury the principle is the same. The aim is to make an instrument which is easily carried, durable and accurate.

In all the mercury instruments the diameter of the tube is 2 mm. One would suppose that there would be notice-

able differences in the readings of the different mercury instruments depending upon the amount of mercury used in the tube. By actual weight there is from 35 to 45 gms. of mercury in the several instruments. After many trials, no noticeable differences in blood pressure readings can be made out between a column weighing 35 gm. and one weighing 45 gm.

There is, however, the inertia of the mercury to be overcome, friction between the tube and the mercury, and vapor tension. The mercury is therefore not as sensitive to rapid changes of pressure in the cuff as a lighter fluid would be. The mercury must be clean and the tube dry so that there is no more friction than what is inherent between the mercury and glass. In making readings on a rapid pulse the oscillations of the mercury column are apt to be irregular or to cease now and then, due to the fact that the downward oscillation coincides with a pulse wave, or an upward oscillation receives the impact of two pulse waves transmitted through the cuff. Instruments have been devised to obviate this difficulty but they have not come into favor. They are usually too complicated and at present can not be recommended.

An instrument devised by Dr. Rogers (the "Tycos") has met with considerable popularity. (Fig. 15.) Contrary to the general belief, this is not an instrument which operates with a spring and lever. The instrument is composed essentially of two metal discs carefully ground and attached at their circumferences to the metal casing below the dial. There is an air chamber between these discs through the center of which air is forced by the syringe bulb. When air is forced into the space between these two discs, they are forced apart to a very slight extent, with the highest pressures only 2-3 mm. of bulging occurs. From data gathered after extensive use for two years these discs

were not found to have sprung. A lever attached to a cog which in turn is attached to the dial needle magnifies to an enormous extent the slightest expansion of the discs. Every dial is handmade and every division is actually determined by using a U. S. government mercury manometer of standard type. No two dials therefore are alike in the spacing of the divisions of the scale but every one is calibrated as an individual instrument. There is no doubt in the author's

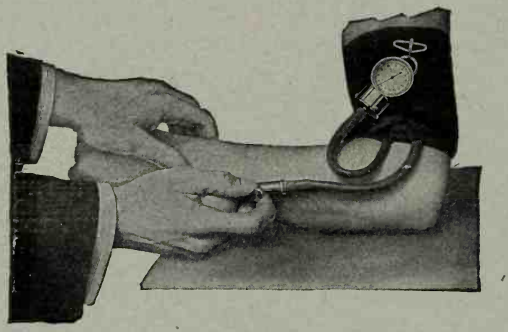

Fig. 15.—Rogers' "Tycos" dial sphygmomanometer.

mind that for the general practitioner the instrument has some advantages over the mercury instruments. It reveals the slightest irregularity in force of the heart beat. The oscillation of the dial needle is more accurately followed by the eye than is that of the column of mercury. The needle passes directly over the divisions of the scale, while with usual mercury instruments the scale is an appreciable distance (sometimes .5 cm.) from the column of mercury at the side. (Fig. 16.) The diastolic pressure is more easily read on the "Tycos." It is where the maximum oscillation of the needle occurs as the pressure is slowly released from the cuff. Although it does not appear that this instrument, if properly made and standardized, could become inaccurate, nevertheless it is advisable to check it every few months against a known accurate mercury manometer instrument.

If it wears well, it will undoubtedly supersede all others on account of its compactness, lightness, and ease of manipulation. Other firms are making instruments something like

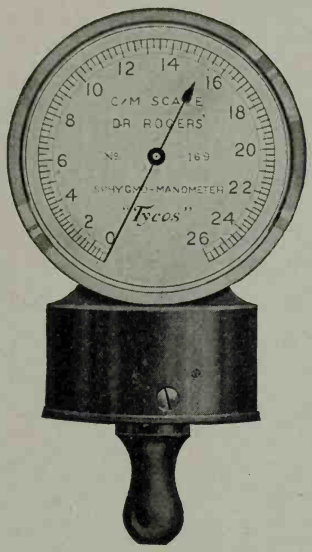

Fig. 16.—Detail of the dial in the "Tycos" instrument.

"Tycos" in appearance. Possibly they are as good. There is this much to be said, no instrument using a spring as resistance to measure pressure can be recommended.

Technique.

The same technique applies to all the mercury instruments. The patient sits or lies down comfortably. The right or left arm is bared to the shoulder, the cuff is then slipped over the hand to the upper arm. (See Fig. 17.) At least an inch of bare arm should show between the lower end of the cuff and the bend of the elbow. The rubber is adjusted so that the actual pressure from the bag is against the inner side of the arm. The straps are tightened, care

being taken not to compress the veins. The upper part of the cuff should fit more snugly than the lower part. The part of the instrument carrying the mercury column is now placed on a level surface; the two arms of the mercury in the tube must be even, and at O on the scale. With the

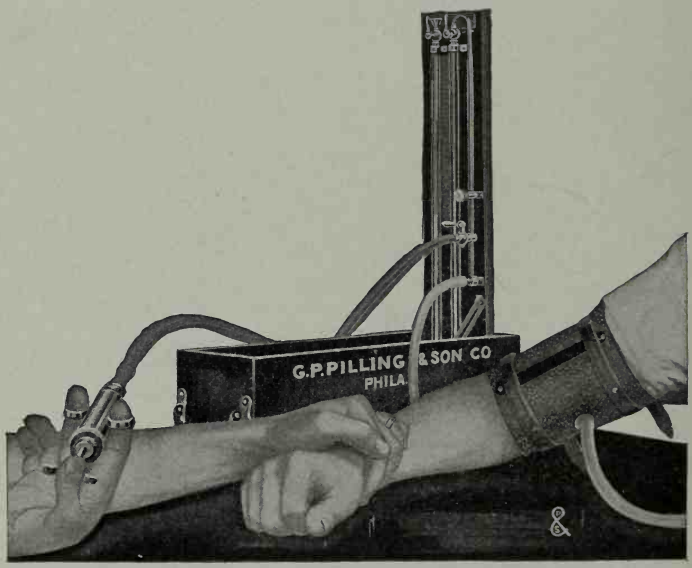

Fig. 17.—Method of taking blood pressure with a patient in sitting position.

fingers of one hand on the radial pulse, the bag is compressed until the pulse is no longer felt. (See Fig. 18.) One should raise the pressure from 10-12 mm. above this, and close the stop cock between the bulb and the mercury tube. In a good instrument the column should not fall. If it does there is a leak of air in the system of tubing and arm bag. Now with the finger on the pulse, or where the pulse was last felt, gradually allow air to escape by turning the stop cock so that the column of mercury falls about 2 mm. (one division on the scale) for every heart beat or two. One must not allow the column of mercury to

descend too slowly as it is uncomfortable for the patient and introduces a psychic element of annoyance which affects the blood pressure. On the other hand, the pressure must not be released too rapidly, else one runs over the points of systolic and diastolic pressure and the readings are grossly inaccurate. It is impossible to say how rapidly the mercury must fall. Every operator must find that out for himself

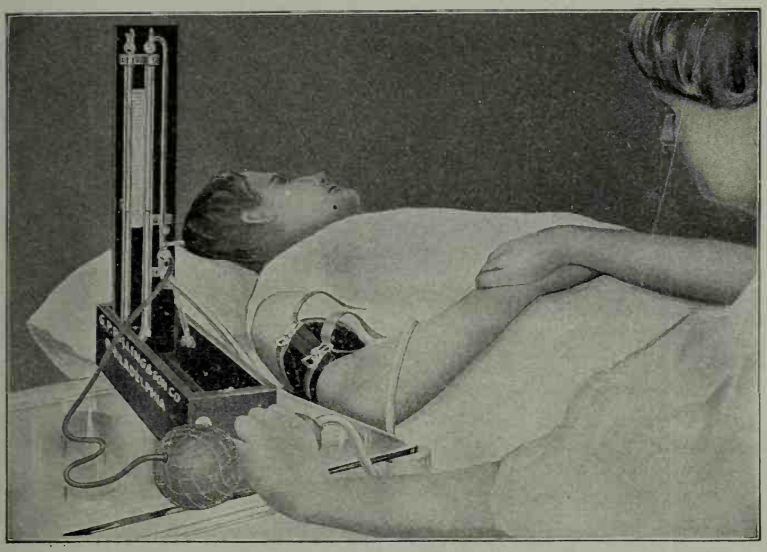

Fig. 18.—Method of taking blood pressure with patient lying down.

by practice. The first perceptible pulse wave felt beneath the palpating finger at the wrist, represents on the scale the systolic pressure. This can be seen to correspond to a sudden increase in the magnitude of the oscillation of the mercury column. The systolic pressure, thus obtained, is from 5-10 mm. lower than the real systolic pressure. The more sensitive the palpating finger, the more nearly does the systolic pressure reading approach that found by using such an instrument as Erlanger's, where the first pulse wave is magnified by the lever of the tambour.

The pressure is now allowed to fall, until the palpating finger feels the largest possible pulse wave, which is coincident with the greatest oscillation of the mercury. This is the diastolic pressure. Beyond this point there is no oscillation of the mercury column. The difference between the two is the pulse pressure. Thus the pulse is felt after compression at 150 on the scale, and the maximum oscillation

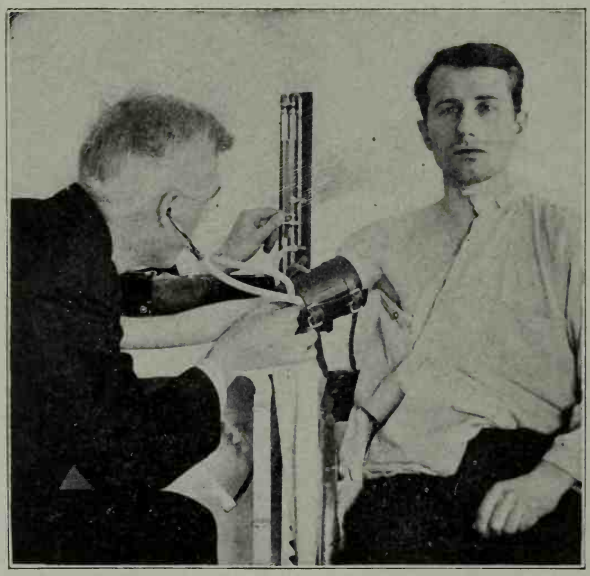

Fig. 19.—Observation by the auscultatory method and a mercury instrument. One hand regulates the stop cock which releases air gradually.

occurs at 110. The systolic pressure is 150 mm., the diastolic is 110 mm., and the pulse pressure is 40 mm.

With the "Tycos" the arm band is snugly wound around the arm, the bag next to the skin and the end tucked in, so that the whole band will not loosen when air is forced into the bag. The valve on the air bulb is now tightly closed and the cuff blown up until the pulse is no longer felt. One should raise the pressure not more than 10 mm. above the point of obliteration of the pulse. The valve is then care-

fully opened so that the needle gradually turns toward zero. At the first return of the pulse wave felt at the wrist, the needle is sure to give a sudden jump. This is the systolic pressure and is read off on the scale. The needle is now carefully watched until it shows the maximum oscillation. This is the diastolic pressure. The difference between the two is, as above, the pulse pressure.

In taking pressure one should take the average of several, three or four. Moreover, one must not take consecutive readings too quickly and one must be sure that between every two readings all the air is out of the cuff and that the mercury or dial is at zero. It has been repeatedly shown that in a cyanosed arm the systolic pressure is raised so that even slight cyanosis between readings must be carefully avoided.

A more accurate method of determining both the systolic and diastolic pressure, but especially the diastolic, is by the so-called auscultatory method. (See Fig. 19.) The cuff is adjusted in the usual way and one places the bell of a binaural stethoscope over the brachial artery from one to two centimeters below the lower edge of the cuff. Care must be taken that the bell is not pressed too firmly against the arm and that the edge of the bell nearest the cuff is not pressed more firmly than the opposite end. For this purpose, one cannot use the ordinary Bowles stethoscope or any of the other much lauded stethoscopes, because the surface of the bell is too large. The diameter of the bell must not be more than twenty-five millimeters, twenty is still better. It is advisable before beginning the observation to locate with the finger the pulse in the brachial artery just above the elbow, so that the stethoscope may be placed over the course of the artery. (Fig. 20.) The first wave which comes through is heard as a click, and occurs at a point on the manometer or dial scale

from 5-10 mm. higher than can usually be palpated at the radial artery. This is the true systolic pressure. By keeping the bell of the stethoscope over the brachial artery while the pressure is falling, one comes to a point when all sound suddenly ceases. This is said to be the diastolic pressure. There is still a question whether this disappearance of sound is the true diastolic or whether it is coincident

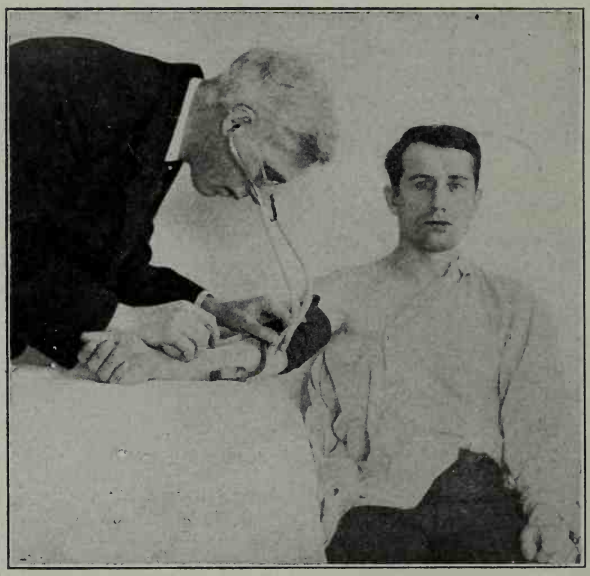

Fig. 20.—Observation by the auscultatory method and a dial instrument. The right hand holds the bulb and regulates the air valve.

with a period just before this. This deserves more extended study. However the weight of present opinion is that the diastolic pressure corresponds to the disappearance of all sounds.

Arterial Pressure.

The arterial pressure in the large arteries undergoes extensive fluctuations with every heart beat. The maximum pressure produced by the systole of the left

ventricle of the heart is known as the **maximum** or **systolic pressure.** It practically equals the intraventricular pressure. The minimum pressure in the artery, the pressure at the end of diastole, is called the **diastolic pressure.** The difference between the systolic and diastolic pressures is known as the **pulse pressure.** There is yet another term known as the **mean pressure.** For convenience, this may be said to be the arithmetical mean of the systolic and diastolic pressures. Actually, however, this cannot be the case, owing to the form of the pulse wave, which is not a uniform rise and fall—the upstroke being a straight line, but the downstroke being broken usually by two notches. We do not make use of the mean pressure in recording results. It is of experimental interest and needs only to be mentioned here.

It has been shown that the mean pressure is quite constant throughout the whole arterial system. The maximum pressure necessarily falls as the periphery of the vascular system is approached. In general it may be said that the minimal pressure is quite constant. Too little attention is paid to minimal and pulse pressure. The minimal pressure is important, for it gives us valuable data as to the actual propulsive force driving the blood forward to the periphery at the end of diastole. Under certain circumstances the minimal pressure is zero. This is the case in marked grades of aortic insufficiency. Here the maximum and pulse pressure are equal and there is great dilatation of the peripheral capillaries with the capillary pulse familiar to all.

It is readily understood how the maximum pressure falls as the periphery is approached, until in the arterioles the maximum and minimum pressures are about equal. The pressure then in these arterioles is practically the same as the diastolic pressure. Actually it is a few millimeters

less. The diastolic blood pressure would, therefore, measure the peripheral resistance and, as the maximum for systolic pressure represents approximately the intraventricular pressure, the difference between the two, the pulse pressure, actually represents the force which is driving the blood onward from the heart to the periphery. It is hence very evident that the mere estimation of the systolic pressure gives us but a portion of the information we are seeking.

The pulse pressure is subject to wide fluctuations but as a rule for any one normal heart it remains fairly constant as the rate varies. In a rapidly beating heart the diastole is short and the diastolic pressure rises. If the systolic pressure does not also rise, as in a normal heart following exercise, we will say, the pulse pressure falls. We know that when the pulse rate is constant, vasodilatation causes a fall in diastolic pressure and a rise in pulse pressure. On the contrary, vasoconstriction causes a rise in diastolic pressure and a fall in pulse pressure.

It is very probably the case that with two individuals of equal age and equal pulse rate, and equal systolic pressure of 160 mm., the one with a diastolic pressure of 140 mm. and, therefore, a pulse pressure of only 20 mm. is much worse off than the other with a diastolic pressure of 110 mm. and a pulse pressure of 50 mm. The latter may be normal for the age of the person, the former is not normal for any age. Low pulse pressure means a weak vasomotor control and is only found in failing circulation or in markedly run down states such as after serious illness or in tuberculosis. Therefore, it is most important to estimate accurately the diastolic pressure as well as the systolic pressure, for only in this way can we obtain any data of value regarding the driving power of the heart and the condition of the vasomotor system. A high systolic pressure does

not necessarily mean that a great deal of blood is forced into the capillaries. Actually it may mean that very little blood enters the periphery. The heart wastes its strength in dilating constricted vessels without actually carrying on the circulation adequately.

Normal Pressure Variations.

The systolic pressure varies considerably under conditions which are by no means abnormal. Thus, the average for men at all ages is about 127 mm. Hg. (All measurements are taken from the brachial artery, with the individuals in the sitting posture.) For women the average is somewhat lower, 120 mm. Hg. The pressure is lowest in children. In children from 6-12 years the average systolic pressure is 112 mm. Normally, there is a gradual increase as age comes on, due, as will be shown in the succeeding chapter, to physiological changes which take place in the arteries from birth to old age. In the chart here appended is graphically shown the normal variations in the blood pressure at different ages compiled from observations made on one thousand presumably normal persons. (Fig. 21.)

The diastolic pressure has been estimated to be about 45 to 48 mm. Hg. lower than the systolic pressure, and consequently these figures represent the pulse pressure in the brachial artery of man. This is equivalent to saying that every systole of the left ventricle distends this artery by a sudden increase in pressure equal to the weight of a column of mercury 2 mm. in diameter and 45 to 48 mm. high. Naturally, at the heart the pressure is highest. As the blood goes toward the capillary area the pressure gradually decreases until, at the openings of the great veins into the heart, the pressure is least. At the aorta (A) the pressure (systolic) is approximately 150 mm. Hg., at the brachial

artery (B) it is 130 mm., in the capillary system (C) it is 30 mm., in the femoral vein (F) it is 20 mm., at the opening of the inferior vena cava (I) it is 3 mm. (Fig. 22.)

Attention has been called to the normal systolic pressure

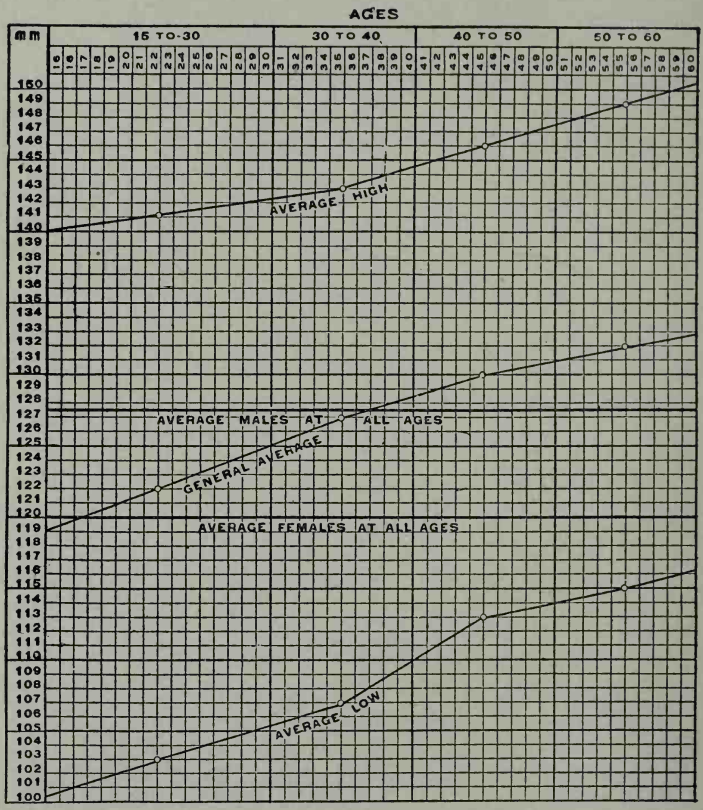

Fig. 21.—Chart showing the normal limits of variation in systolic blood pressure. (After Woley.)

at different ages. This is not the only cause for variations in the blood pressure. Normally, it is greater when in the erect position than when seated, and greater when seated than when lying down. During the day there are well-recognized changes. The pressure is lowest during the

early morning hours, when the person is asleep. In women there are variations due to menstruation. Muscular exercise raises the blood pressure markedly. The effect of a full meal is to raise the blood pressure. The explanation is that during and following a meal there is dilatation of the abdominal vessels. This takes blood from other parts of the body, provided that the other factors in the circulation remain constant. A fall of pressure would necessarily occur in the aorta. To compensate for this, there is increased work on the part of the heart, which reveals itself

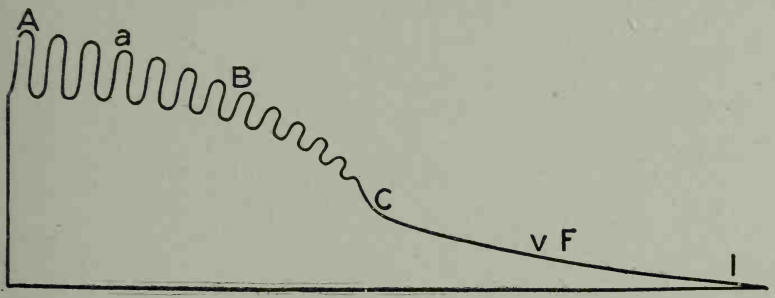

Fig. 22.—Schema to illustrate the gradual decrease in pressure from the heart to the vena cava: (a), arteries; (c), capillaries; (v), veins; (A), aorta, pressure 150mm.; (B), brachial artery, pressure 130mm.; (F), femoral vein, 20mm.; (IVC), inferior vena cava, 3mm. (Modified from Howell.)

as increased pressure and pulse pressure. It is well known that the interest in the process taken by an individual upon whom the blood pressure is estimated for the first time tends to increase the rate of the heart and to raise the blood pressure. For this reason the first few readings on the instrument must be discarded, and not until the patient looks upon the procedure calmly can the true blood pressure be obtained. As a corollary to this statement, mental excitement, of whatever kind, has a marked influence on the pressure. The patient must remain absolutely quiet. Raising the head or the free arm causes the pressure to rise. Another important physiological variation is produced by

concentrated mental activity. This tends to hurry the heart and increase the force of the beat. In short, it may be stated as a general rule that any active functionating of a part of the body which naturally requires a great excess of blood tends to elevate the blood pressure. At rest the pressure is constant. Variations caused by the factors mentioned act only transitorily, and the pressure shortly returns to normal.

The Auscultatory Blood Pressure Phenomenon.

When one applies the 12 cm. arm band over the brachial artery and listens with the bell of the stethoscope about one cm. below the cuff over the brachial artery, an interesting series of sounds are produced as one passes from the systolic maximum pressure to the diastolic minimum pressure. "The cycle begins with the passage of the first waves of blood under the cuff. This produces a clear-cut sound resembling the tap of embryocardial rhythm, and is known as the first phase. Succeeding this a murmur becomes audible, more or less clearly defined and of varying duration. In the average case the murmur at first accompanies the sound, but soon replaces it. The period of audible murmur is known as the 'second phase.' At the inception of the next or third phase the murmur disappears and is substituted by a clear sound. With the further fall of the mercury this clear sound becomes dull. At times this transformation is clear-cut and easily recognizable, again, it occurs more gradually. Ettinger and Fischer describe this transformation as the 'fourth phase.' The latter believes that it coincides with the diastolic pressure. Ettinger considers that it precedes true diastole, and that the latter coincides with the disappearance of all sounds, which he calls the 'fifth phase.'" (Gittings.)

The first phase is due to the sudden expansion of the collapsed portion of the artery below the cuff and to the rapidity of the blood flow. This causes the first sharp clicking sound which measures the systolic pressure.

The second, or murmur and sound phase, is due to the whorls in the blood stream as the pressure is further released and the part of the artery below the cuff begins to fill with blood.

The third tone phase is due to the greater expansion of the artery and to the lowered velocity in the artery. A loud tone may be produced by a stiff artery and a slow stream or by an elastic artery and a rapid stream. This tone is clear cut and in general is louder than the first phase.

The fourth phase is a transition from the third and becomes duller in sound as the artery approaches the normal size.

The fifth phase, no sound phase, occurs when the pressure in the cuff exerts no compression on the artery and the vessel is full throughout its length.

It is generally conceded that the sounds heard are produced in the artery itself and not at the heart.

The tones vary greatly in different hearts. A very strong third tone phase or prolongation of this phase usually means that the heart which produces the tone is a strongly acting one, although allowances must be made for a sclerosed artery in which there is a tendency to the production of a sharp third phase.

Weakness of the third phase, as a rule, indicates weakness of the heart and this dulling of the third phase may be so excessive that no sound is produced. Goodman and Howell have carried this method further by measuring the individual phases and calculating the percentage of each phase to the pulse pressure. Thus, if in a normal individual the systolic pressure is 130 mm., the diastolic 85 mm., and the

pulse pressure 45 mm., the first phase lasts from 130 to 116 or 14 mm., the second from 116 to 96, or 20 mm., the third from 96 to 91 or 5 mm., the fourth from 91 to 85, or 6 mm. The first phase would then be 31.1 per cent of the total pulse pressure, the second phase 44.4 per cent, the third phase 11.1 per cent, and the fourth phase 13.3 per cent. They consider that the second and third phases represent cardiac strength (C. S.) and the first and fourth represent cardiac weakness (C. W.). They believe that C. S. should normally be greater than C. W. In the example above C. S.: C. W.= 55.5: 44.4. In weak hearts, especially in uncompensated hearts, the conditions are reversed and C. W. > C. S. This is actually the case. As a heart improves C. S. again becomes greater than C. W. They think that the phases should be studied in respect to the sounds and also to the encroachment of one sound upon another.

A further interesting feature which can be heard in all irregular hearts is a great difference in intensity of the individual sounds. Goodman and Howell call this phenomenon tonal arrhythmia. Irregularities can be made out by the auscultatory method which can not be heard at the heart.

In anemia the sounds are very loud and clear and do not seem to represent the actual strength of the heart. I have in my records such a reading:

Lymphatic leukemia. Patient aged 54, weak and failing. Red blood corpuscles 3,420,000; white cells 100,000; hemoglobin 38 per cent. Systolic pressure 104 mm., diastolic pressure 64 mm., pulse pressure 40 mm. C. S.: C. W.= 72.5: 27.5.

In this particular case the heart sounds were faint and the heart evidently was weak.

In polycythemia the sounds have a curious, dull, sticky character and can not be differentiated accurately into

phases, a condition which was predicted from the knowledge of the sharp sounds in anemia.

This work of Goodman and Howell needs confirmation but is of sufficient interest and importance to merit the extended mention given it.

In not all cases can all phases be made out. It is usually the fourth phase which fails to be heard. Personal observations lead me to believe that the third phase or the fourth phase, when heard, represents the diastolic pressure, for simultaneous tracings on the kymograph show that the maximum oscillation of the mercury occurs here. At the fifth phase there is no brachial pulse beat which is registered on the drum. This needs further study.

"In arteriosclerosis, with hardening and loss of elasticity of the vessel walls, the auscultatory phenomena, according to Krylow, are apt to be more pronounced, since the back pressure at the cuff probably causes some dilatation of the vessel above it, while the lumen of the vessel is smaller than normal. Both of these factors cause an increased rapidity in the transmission of the blood wave when pressure in the cuff is released, which in time favors the vibration of the vessel walls.

"In high grade thickening of the arterial walls, however, especially where calcification had occurred, Fischer found that the sounds were distinctly less loud than normal, the more so in the arm, which showed the greater degree of hardening. According to Ettinger's experience, the rapidity of the flow distinctly increases the auscultatory phenomenon."[1] (Gittings.)

The sounds depend upon the resonating character of the cuff, upon the size and accessibility of the vessel, upon the force of the heart beat, and upon the velocity of the blood.

[1] For a full discussion of this subject the reader is referred to J. C. Gittings' article in Archives of Internal Medicine, 1910, VI, 196.

Changes in Blood Pressure.

Experimentally, certain drugs—such as adrenalin, barium chloride, nicotine, etc.—raise the blood pressure. Shock and hemorrhage lower it. Hemorrhage lowers also the pulse pressure, and it may be possible to prognosticate internal hemorrhage by frequent estimations of the systolic and diastolic pressures. (Wiggers.) Compression of the superior mesenteric artery or the celiac axis in dogs raises the blood pressure measured in the carotid artery for a period of at least an hour. This seems to be dependent on purely mechanical causes, and is not a reflex vasomotor phenomenon. (Longcope and McClintock.)

One most important condition which causes increased blood pressure is intracranial tension. This may be brought about by edema of a part or the whole brain, extra- and subdural hemorrhages the results of head injuries, tumors within the skull which do not replace brain tissue as they grow. Cushing has shown that very high blood pressure can be produced experimentally in dogs by compression of the brain and this applies directly to man. The increase in pressure is due to compression of the medulla and consequent anemia of the vasomotor centers. This acts as a vasoconstrictor stimulus and the blood pressure is raised to a point where the medulla is supplied with blood. Too high and too prolonged compression of the medulla brings about exhaustion of the centers with rapid pulse, low pressure, and death from asphyxia.

Should any of the conditions mentioned above (excepting of course increased intracranial tension) act over prolonged periods, then there might result permanent increase of blood pressure. This is readily understood from what has been said of the normal variations in pressure.

Hypertension.

When the systolic pressure is constantly above the normal for the age and sex of the individual, it is spoken of as hypertension. Hypertension in certain cases is a relative term. A man with systolic pressure of 160 mm. Hg. would at once be said to have hypertension. If, however, the age, the circumstances under which the measurement was taken, etc., were known, it might not be actual hypertension. The patient may have been a strong, elderly man, or the pressure may have been measured in a young man during excitement, after meal, or after exercise. Prolonged hypertension is not a normal state, and sooner or later there must result changes in the circulatory system. Changes actually do occur in both the heart and arteries, leading to the production of arteriosclerosis and to the establishment of a vicious circle.

Undoubtedly the greatest blood pressure values are to be seen in cases of chronic interstitial nephritis, where the systolic pressure reaches 270 mm. of mercury or even higher. Not all diseases of the kidney, however, cause increased blood pressure. It is frequently absent in the toxic nephritis cases and in those caused by certain of the infectious diseases. However, in primary acute Bright's disease, which is probably infectious in character, and in the nephritis secondary to scarlet fever, there is practically always an increase in the arterial pressure. This rise may amount to 50 mm. of mercury within forty-eight hours of the onset of the disease.

Certain forms of arteriosclerosis cause a permanent increase in blood pressure and are accompanied by heart hypertrophy. When there is arteriosclerosis of the peripheral arteries, which is characterized by early calcification of the media, with little or no change in the intima, the

blood pressure is not increased. As long as the aorta retains its normal elasticity, it seems to be able to protect the heart and to assist in forcing the blood through the narrowed peripheral vessels. It is only when there is associated sclerosis of the aorta (an intimal sclerosis), especially of the first part, that the left ventricle hypertrophies and hypertension results. Extensive sclerosis of the splanchnic vessels also appears to cause hypertrophy of the left ventricle. When the elasticity of the arteries is diminished, they offer a greater resistance to dilating forces, but, once having been dilated, they do not so easily recover their original size. The rigidity of certain areas may be neutralized by dilatation of other areas. But the splanchnic arteries are of such paramount importance in the regulation of the peripheral resistance that disease in them renders it difficult or impossible for dilatation in other parts of the body sufficiently to compensate for the splanchnic contraction.

Elliott, in an interesting comparison of the blood pressure in pure arteriosclerosis and in chronic nephritis, arrived at the following conclusions: (1) the ordinary clinical type of arteriosclerosis is not necessarily accompanied by high blood pressure; (2) where high blood pressure is met with in arteriosclerosis, it points to the existence either of associated renal disease, or of sclerosis of the splanchnic vessels and of the aorta above the diaphragm, or both; (3) if we can exclude the renal disease (chronic), splanchnic or aortic sclerosis is to be suspected.

If it were not for the so-called tone of the whole vascular area, the heart could not maintain the circulation. This tone is maintained by the contraction of the involuntary muscle in the vessels. There are both vasoconstrictor and vasodilator fibers from the sympathetic nervous system to the smooth muscle fibers of the arteries. The splanchnic

area is relatively poorly supplied with the dilator fibers. The continuous constrictor impulses sent out from the sympathetic ganglia along the dorsal spine to the arteries keep the vessels in a state of constriction sufficient to offer enough resistance to the blood flow to facilitate the work of the heart without placing, for any prolonged period, a great strain upon it.

It is, therefore, conceivable that an increase in blood pressure may come about in two ways: (1) by stimulation of the constrictor center (or centers?); (2) by the direct action of poisonous products circulating in the blood on the muscle cells in the arterial walls. It is believed that the active principle from the medulla of the adrenal gland, adrenalin, is responsible for the maintenance of the arterial tone.

It has also been discovered that the extract from the infundibular part of the pituitary body causes an elevation of the blood pressure. It would appear that there is an intimate association among the ductless glands of the body. It has also been found that at various places in the body there are collections of cells known as chromaffin cells, which apparently have an internal secretion analogous to, if not the same as, the active principle of the adrenal gland. A group of these cells discovered in the heart has been found to be much hypertrophied in a case of chronic interstitial nephritis, accompanied with increased blood pressure and heart hypertrophy.

Clinically, we know that adrenalin causes a rise in the blood pressure. Experimentally, as has been shown, adrenalin not only is able to cause a rise in blood pressure, but also a degeneration of the muscle layer, with consequent production of lesions resembling to some extent those of arteriosclerosis in man.

While it must not be forgotten that, given an equal

peripheral resistance, a rapid heart will cause the blood pressure to rise, nevertheless this condition usually does not last long. Practically all cases of permanent high tension are due to increase of the peripheral resistance.

Hypotension.

When the pressure is constantly below the normal, it is called hypotension. This may be transient—as in fainting—it may be a normal state of the individual, it occurs in most fevers and in a great variety of diseases, including anemias.

In arteriosclerosis, especially the diffuse (senile) type, the blood pressure is invariably low, and may be spoken of as hypotension. The heart in such a case is small, the muscle is flabby, there is brown atrophy of the fibers, and some replacement of the muscle cells by connective tissue. The same causes which have produced general arteriosclerosis have also produced sclerosis of the coronary arteries, and probably the lessened blood supply accounts for much of the atrophy of the heart muscle.

In typhoid fever the maximum blood pressure during beginning convalescence may be as low as 65 mm. Hg. I have frequently seen hypotension of 80 mm. This is common.

Meningitis is the only acute infectious disease in which the blood pressure is more often high than low. This is accounted for by the increased intracranial tension.

Following large hemorrhages the blood pressure is reduced. In venesection the withdrawal of blood may not affect the blood pressure as the procedure is done to relieve overdistension of the heart.

In pleurisy with effusion and in pericarditis with effusion there is hypotension.

Collapse, whether from poisoning by drugs or as the result of dysentery, cholera, or profuse vomiting from whatever cause, reduces the blood pressure.

In cachectic states, such as cancer, the blood pressure is low. General wasting of the whole musculature includes that of the heart and the heart muscle shows the condition known as "brown atrophy."

A most interesting and important condition in which hypotension occurs is pulmonary tuberculosis. Haven Emerson has recently gone over the whole subject in a careful piece of work and his summary is as follows:

"Hypotension or subnormal blood pressure is universally found in advanced pulmonary tuberculosis, in which condition emaciation may play a part in its causation. Hypotension is found in almost all cases of moderately advanced tuberculosis, or in early cases in which the toxemia is marked except when arteriosclerosis, the so-called arthritic or gouty diathesis, chronic nephritis, or diabetes complicate the tuberculosis and bring about a normal pressure or a hypertension. Occasionally the period just preceding a hemoptysis or during a hemoptysis may show hypertension in a patient whose usual condition is that of hypotension.

"Hypotension has been found by so many observers in early, doubtful or suspected cases with or before physical signs of the disease in the lungs, and is considered by competent clinicians so useful a differential sign between various conditions and tuberculosis, that it should be sought for as carefully as it is the custom at present to search for pulmonary signs.

"Hypotension when found persistently in individuals or families or classes living under certain unhygienic conditions should put us on our guard against at least a predisposition to tuberculosis. Most unhygienic conditions,

overwork, undernourishment and insufficient air, are of themselves causes of a diminished resistance, and it seems likely that a failure of normal cardiovascular response to exercise or change of position may be found to indicate this stage of susceptibility, especially to tuberculous infection.

". . . Hypotension, when it is present in tuberculosis, increases with an extension of the process. Recovery from hypotension accompanies arrest or improvement. Return to normal pressure is commonly found in those who are cured. Continuation of hypotension seems never to accompany improvement. Prognosis can as safely be based on the alteration in the blood pressure as on changes in the pulse or temperature. . . ."

There are a few drugs which lower the blood pressure, but, as a rule, their effects are more or less transitory. We know of no drug, unless it be iodide of potassium, which has the property of causing changes in the blood (decrease in viscosity?), which tends to reduce the blood pressure when it is excessive. This drug fails us many times.

SOME DRUGS WHICH INFLUENCE THE BLOOD PRESSURE.

Pressure Raisers.

Adrenalin, when injected directly into a vein or deep into the muscles. The action is transitory.

Caffeine, preferably in the form of caffeine-sodium-benzoate. A good drug.

Strychnine, which does not act directly but seemingly through the higher centers.

Ergot, somewhat uncertain.

Nicotine, not used therapeutically.

Camphor, used in sterile olive oil and injected deeply into the muscles.

Digitalis, when the cardiac tone is low and decompensation is present. Its action is prolonged but slow. Injections of the infundibular portion of the pituitary body. Not in use clinically.

Pressure Depressors.

Nitroglycerine and amyl nitrite, action transitory but rapid.

Sodium nitrite and erythrol tetranitrate. Action somewhat more prolonged.

Aconite, veratrum viride, chloral, etc. These depress the heart.

Purgatives, drastic and hydragogue.

Potassium and sodium iodide may lower blood pressure. When they do, the action is prolonged.

Diuretin and theocin-sodium-acetate.

Venous Pressure.

Up to the present time very little work has been done upon the determination of the pressure in the veins in man. It is conceivable that this procedure may, at times, be of great value. A number of attempts have been made to measure the venous pressure by compressing the arm veins and noting on a manometer the force necessary to obliterate the vein. As the pressure is so slight, water is used instead of mercury, and readings have been given in centimeters of water.

In the apparatus shown in the figure (Fig. 23), Drs. Hooker and Eyster succeeded in making estimations of the venous pressure. The box B is held in position by the tapes A, so that the vein is visible through the rectangular opening in the thin rubber covering the bottom. The box is connected with the water manometer G, by a rubber tube, from which a T-tube enters the rubber bulb E. When the bulb E is compressed between the plates D, by the coarse thumbscrew C, air is forced into the box B, exerting a pressure on the vein lying exposed beneath. This pressure is transmitted directly to the manometer G, and may be read off in centimeters of water on the accompanying scale. The veins of the back of the hand are used and there must be no obstruction between them and the heart. The rubber-covered box is accurately and lightly fitted over a vein and pressure made until it is obliterated. By measuring the distance above or below the heart level that the hand was when the observation was made, and subtracting or adding these figures to the manometer reading, we obtain the venous pressure at the heart level.

Practically Hooker and Eyster found that the normal variation in healthy subjects was from 3 to 10 cm. of water. The pressure rose in cases of decompensated hearts with

dyspnea and venous stasis, and returned to normal with improvement in the condition of the patient. It might be possible with this instrument to foretell an oncoming decompensation by the rise in venous pressure.

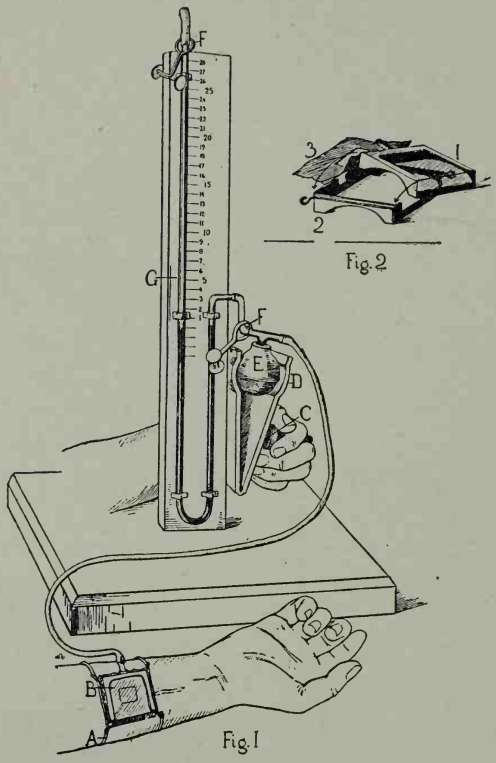

Fig. 23.—Apparatus for estimating the venous blood pressure in man, devised by Drs. Hooker and Eyster. The small figure is the detail of the box B. See explanation in text.

The venous pressure may also be estimated roughly by slowly elevating the arm and noting the instant at which a particular vein collapses. By measuring the height of the vein above the heart some idea may be obtained of the pressure within the right auricle.

Blood Pressure in Surgery.

Attention has already been drawn to the value of blood pressure estimations in cases of head injury.

Sudden pain in any part of the body temporarily raises the blood pressure, which, however, soon falls to normal or below normal. The fall is especially great in cases of peritonitis. It can be said that in any acute abdominal condition, the gradual fall of blood pressure is a bad omen and is an indication for surgical procedures.

Anesthetics at first cause the blood pressure to rise above the normal. This is particularly true of ether. Chloroform even comparatively early, however, depresses the pressure and if for no other reason it is not as safe an anesthetic as is ether. After the patient is well under the anesthetic, the blood pressure becomes stationary at a point slightly above the normal as long as the anesthetic is properly administered. A fluctuating blood pressure usually indicates that the anesthetizer is not properly doing his work.

Handling and manipulation of the viscera, and traction on the parietal peritoneum, cause the pressure to fall and aid in the production of shock. The more rough the manipulation, the greater the fall of blood pressure. Exposure of loops of intestine on the surface of the abdomen assists in producing shock. This is prevented by laying hot, wet cloths over the exposed loops. Particularly dangerous are operations around the larynx, as shock is easily produced. This may be prevented by cocainization of the nerve endings in the larynx.

In any operation where there is any question of shock or collapse, there should be some assistant (the anesthetizer can act in this capacity), who takes frequent estimations of the blood pressure. This can readily be done without

disturbing the surgeon in his work. An arm of the patient is stretched out perpendicular to the body and is rested on a table. The cuff is placed around the arm in the usual way, and either by palpating the radial artery or by using the stethoscope over the brachial artery, the pressure can be taken from time to time. Five minute intervals are convenient. Any sheet of paper ruled in small squares, such as the ordinary temperature chart, or a special blood pressure chart is taken and a base line made of normal pressure for the individual. A dot is made in every square at the point corresponding to the pressure in millimeters of mercury and by joining the dots a curve of pressure is made for periods before, during, and after the operation. This really is a most important, but unfortunately much neglected, function of the sphygmomanometer. Many a patient could be saved were it known that shock were impending. This can certainly be foretold in practically all cases by the intelligent use of the instrument.

In the new operation of direct transfusion of blood, blood pressure estimations upon the donor and recipient will assist in determining when to cease the transfusion.

Again the routine use of the instrument will give us information as to whether our therapeutic procedures are of the proper kind. This is of great importance in the after treatment of cases of peritonitis.

The Pulse.

There is nothing characteristic about the pulse of a person suffering from arteriosclerosis, except it be the difference in the pulse of high tension and of low tension. The pulse of high tension has a gradual rise, a more or less rounded apex, and the dicrotic wave is slightly marked and occurs about half-way down on the descending limb. In

arteriosclerosis with low tension the radial artery is usually so rigid that very little pulse wave can be obtained. The general form of a low tension pulse is a sharp up-stroke, a pointed summit, and a secondary wave on the base line, which corresponds to the dicrotic wave. Such a pulse can be easily palpated, and is known as a dicrotic pulse. However, such a pulse can occur only when the artery still retains all or a large part of its elasticity; hence in arteriosclerotic low tension we would never see such a pulse as the typical dicrotic.

The Venous Pulse.

It would carry us too far to discuss fully the character of the venous pulse, but a brief summary of the essential features of the normal venous pulse is presented. The venous pulse is a term used to express the tracing obtained from the internal or external jugular vein at the root of the neck. Normally a very characteristic curve is produced, which can be readily analyzed into a series of waves corresponding to the fluctuations in the cardiac cycle. To understand these waves and their values, the accompanying figure is helpful. (Fig. 24.)

Bachmann summarizes the normal waves in the venous pulse tracing as follows:

"The physiological or so-called venous pulse consists of three positive and three negative waves, bearing a more or less definite relation to the events of the cardiac cycle, and having their origin in the various movements of the chambers and structures of the right heart. The first positive wave (a) is presystolic in time, and is due to the contraction of the auricle, causing a slowing of the venous current and producing a centrifugal wave through a sudden arrest of the inflowing blood. The second positive wave (S) is

presystolic in time, and originates in the sudden projection of the tricuspid valve into the cavity of the auricle during the quick, incipient rise in the intraventricular pressure occurring in the protosystolic period. The third positive wave (v) occurs toward the end of ventricular systole. It consists of two lesser waves separated by a shallow notch.

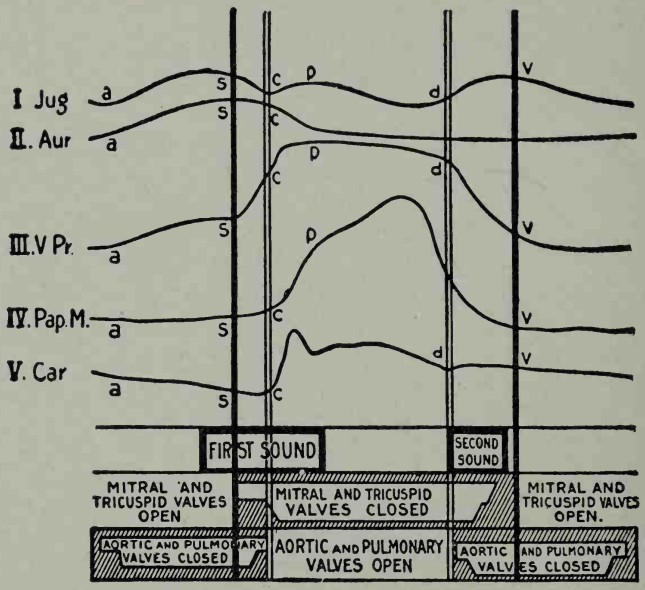

Fig. 24.—Semidiagrammatic representation of the events in the cardiac cycle: Jug., pulse in the jugular vein; Aur., contraction of auricle; V. Pr., intraventricular pressure; Pap. M., contraction of the papillary muscles; Car., carotid pulse. Below are given the times of occurrence of the heart sounds and of the opening and closing of the heart valves. (After Hirschfelder.)

The factors entering into its formation are the relaxation of the papillary muscle at a time when the intraventricular is still higher than the intraauricular pressure, resulting in an upward movement of the tricuspid leaflets and a return of the auriculoventricular septum to its position of rest.

"The first negative wave (between positive wave a and S) is due to the relaxing auricle. The second negative

wave (Af) occurs during the diastole of the auricle. It is due to the dilatation of its walls, to the displacement of the auriculoventricular septum toward the apex occurring at the time of ventricular systole, and to the pull of the papillary muscles on the tricuspid valve leaflets. The third negative wave (Vf) appears during ventricular diastole and in the common pause of the heart chambers. Its cause is found in the passage of the blood from the auricle into the ventricle. It is somewhat modified possibly by the continual ascent of the auriculoventricular septum and by a wave of stasis due to the accumulation of blood coming from the periphery." (Fig. 25.)

Hirschfelder has described another wave which he calls the "h" wave, which is due to the floating up of the tricuspid valve by the blood in the ventricle before the complete filling of the ventricle following the auricular systole. (Fig. 26.)

Heart Block.

As heart block occurs frequently in cases characterized by extensive arteriosclerosis, a brief discussion of the essential features will be given. It is, however, probable that arteriosclerosis is not the cause of any of the cases of heart block directly, but it is only a result of the same etiological conditions which produce the lesion or lesions which result in heart block. We may define heart block as the condition in which the auricles and ventricles beat independently of each other. There may be a partial or complete heart block. In the former there are ventricular silences, during which the auricles beat two, three, four, five, even up to nine times, with only one ventricular contraction. It is believed by most physiologists that the essential factor in the production of heart block is an interference in the conduction of impulses from the auricles to the ventricles through

the band of tissue known as the auriculoventricular bundle.

The bundle of muscles described by His in 1905, connecting the auricles and ventricles, has been definitely

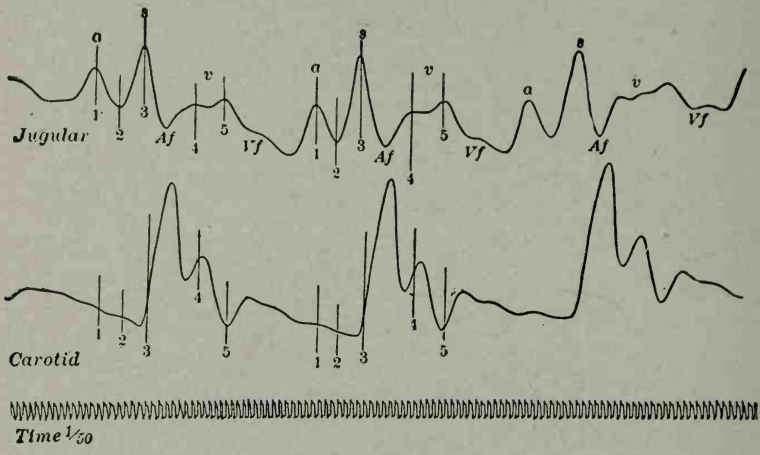

Fig. 25.—Simultaneous tracings of the jugular and carotid pulses showing normal waves in the venous pulse and relation to carotid pulse. (After Bachmann.)

shown to be the path through which impulses having their origin in the orifices of the great veins pass to the ventricles. The situation and size of this bundle has been thus described in man by Retzer:

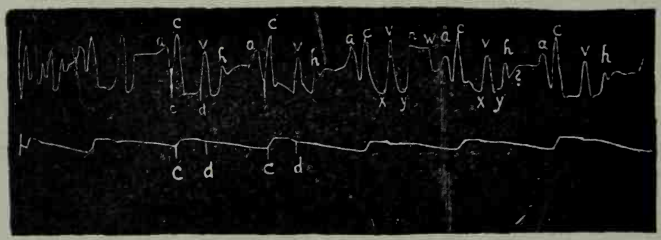

Fig. 26.—Jugular and carotid tracing from a normal individual with a well-marked third heart sound showing a large "h" and a smaller pre-auricular wave "w." ? indicates a small wave in mid-diastole following the "h" wave, occasionally found though perhaps an artefact. (After Hirschfelder.)

"When viewed from the left side, the bundle lies just above the muscular septum of the ventricles and below the

membranous septum. In some hearts the muscular septum is so well developed that it envelopes the bundle. It is then difficult to find it, but occasionally it can be seen directly by means of transmitted light. From the left side the bundle can be followed no farther posteriorly than the right fibrous trigone, for here the connective tissue becomes so dense that it is difficult to dissect it away. The impression is, therefore, received that this mass of connective tissue forms the insertion of the bundle. The bundle may be followed anteriorly until it becomes intimately mixed with the musculature of the ventricles.

"When viewed from the right side of the heart, the bundle cannot be seen, because it is covered by the mesial leaflet of the tricuspid valve, whose line of attachment passes obliquely over the membranous septum. Then, if the endocardium is removed from the posterior part of the septum of the auricle up to the membranous septum, the posterior part of the auriculoventricular bundle will be exposed. If, in addition, the membranous septum be removed, the bundle may be traced from the point to which it could be followed when viewed from the left side as it passes posteriorly over the muscular septum. In the region of the auriculoventricular junction it loses its compactness, the fibers divide, and the bundle seems to fork. One branch passes into the superficial part of the valve musculature which descends from the auricles, and the other branch passes directly into the musculature of the auricle.

"Briefly, the auriculoventricular bundle runs posteriorly in the septum of the ventricles about 10 mm. below the posterior leaflet of the aortic semilunar valves; with a gentle curve it passes posteriorly just over the upper edge of the muscular septum and sends its fibers into the musculature of the right auricle and of the auricular valves. In

the heart of the adult the bundle is 18 mm. long, 2.5 mm. wide, and 1.5 mm. thick." (Erlanger.)

It is now believed that impulses have their origin in the musculature of the great veins at their openings into the auricles of the right heart. Contraction of the heart, as shown by cardiograms and venous pulse tracings, moves in a wave toward the ventricles through the bundle of His. By experimentally compressing the bundle in the heart of the dog, there is at once a marked disturbance in the relation of the auricular and ventricular contractions. This blocking of impulses may be only partial, when the auricle beats, as has been said, from two to nine times to one time of the ventricle, to complete block, when the two chambers beat quite independently.

In any stage of partial block the auricles and ventricles may be completely inhibited by stimulation of the vagus nerve. In complete block, stimulation of the peripheral end of the vagus affects only the auricles, but has little or no influence upon the force of the ventricular beats. The loss of influence of the vagi over the ventricles is always exactly synchronous with the establishment of complete heart block. Even when the heart block is complete, stimulation of the accelerator nerve, as a rule, increases the rate of both auricles and ventricles.

Atropin, as would naturally be inferred from its action on the terminations of the vagus nerve, has no effect on the ventricles of a heart when in the condition of heart block.

CHAPTER IV.

ETIOLOGY.

The causes of arteriosclerosis are many and varied. No two persons have the same resisting power toward poisons that circulate in the blood. Some go through life exposed to all the infectious diseases without ever becoming infected, while others fall easy victims to every disease that comes, no matter how careful they may be, and it is quite the same in regard to the resistance of the arterial tissues. If the tubing is of first class quality and the individual does not place too much strain on it, he may live to the biblical three-score years and ten, and possess arteries which have undergone such slight changes that they are not palpable. Such a person is, however, the exception. On the other hand, if the tissue is of poor quality, even the ordinary wear and tear of life causes early changes in the vessels, and a person of forty may have hard arteries.

We have described in a previous chapter the changes which normally occur in the arteries as age advances. An artery that is normal for a man of fifty years would be distinctly abnormal for a boy of fifteen.

Two broad divisions of arteriosclerosis may be made: (1) congenital, or the result of inherited tendency; (2) acquired.

Congenital Form.

When Dr. O. W. Holmes was asked how to live to the age of seventy, he replied that a man should begin to pick his ancestors one hundred years before he was born. Our parents determine the character of the tissues with which

we start in life, and this determines our general resistance. We might properly speak of congenital arteriosclerosis where the affected individual had poor arterial tissue with which to begin life, for that, in a sense, is a congenital defect, and arterial tissue that is poor in quality is prone to disease.

The author is more and more impressed with the part that heredity plays in the determination of arterial degeneration. Especially does syphilis in the parents or grandparents leave its stigma in the succeeding generations in the shape of poor arterial tissue which is prone to early degeneration. Recently W. W. Graves has called attention to a malformation of the vertebral border of the scapula which consists in a concavity instead of the normal convexity of the bone. To this malformation he has given the name, scaphoid scapula. He considers this to be but one manifestation of a general lack of development in the individual. He speaks of this maldevelopment as a blight and considers that syphilis in the ancestors is responsible for the condition in the offspring. He finds that even in children, the subjects of the scaphoid scapula, the arteries are very definitely thickened. While confirmation of his observations is lacking, there is no doubt that we must lay the blame for much of the arteriosclerosis in our patients to the poor quality of arterial tissue transmitted by ancestors who have acquired some constitutional disease. It may have been syphilis, it may have been the degeneration produced by alcohol or other drug. We cannot ignore the part which heredity plays. The various factors to be considered in the production of the acquired form of arteriosclerosis appear to me to be but contributory factors to a very great extent, the essential and fundamental factor being the quality of arterial tissue with which the individual is endowed.

Arteriosclerosis may occur in infants. Cases have been reported of calcification of the arteries in infants and children. The arteriosclerosis may occur without nephritis or rise of blood pressure. Cerebral hemorrhage in a child of two years has been seen. Heredity in these cases plays a most important rôle. In many of the reported cases there was no question of congenital syphilis. Aneurysms, single or multiple, have been found in the arteries of children, and even the pulmonary artery may show sclerotic changes.

Acquired Form.

As a rule the cases usually seen belong in this group because it seems as if a connection could be established almost always between one or more of the etiological factors to be described and the disease. While this apparently is the case, we must never lose sight of the part which the quality of the tissue plays. When we leave this out of our calculations we undoubtedly make many false deductions. When two men of the same age who have been exposed to the same conditions as far as we can learn, are found to have quite different arteries, the one normal, the other thickened, we must postulate congenitally poor tissue on the part of the latter. Such tissue readily becomes diseased following conditions which would very likely have produced no noticeable effect on perfectly normal, healthy tissue.

Hypertension.

Hypertension holds first place as a cause of arteriosclerosis. With every systole of the heart, blood is forced out into the arterial system against a certain amount of resistance represented by the tonicity of the capillary area, and the amount of cohesion between the viscous blood and

the walls of the arterioles. When a dilatation of the capillaries over any large area takes place, the blood pressure falls, providing there is no compensatory contraction in other areas to make up for the decreased resistance in the dilated vessels. The viscosity of the blood, as such, probably has very little effect on the resistance to the flow. With the systole of the heart there is a sudden dilatation of the arch of the aorta, and a wave of expansion follows, which is transmitted to the periphery and is lost only in the capillaries.

The blood pressure is constantly changing. Physiologically there are relatively wide variations in the pressure in a perfectly normal individual. There are some persons who have hypotension, a blood pressure much below the normal. Such persons have usually small hearts, small aortas, and they seem to have but little resistance to disease. Many diseases, especially the prolonged fevers, diminish markedly the blood pressure. Whether the hypertension is the cause of the structural changes that are found in the walls of the vessels, or is the result of the diminished area of the arterial tree through which the same amount of blood has to be driven as before the vessel walls became narrowed, is still disputed. As has been stated, experimental evidence would tend to place the initial blame upon the poisons circulating in the blood, which first damage the vessel walls. The subsequent changes then produce thickening and inelasticity. Some think (Allbutt) that the hypertension is primary. There are cases seen clinically that lend support to this view and there is experimental evidence also (v. chap. ii). Not infrequently individuals in middle life begin to show increase of arterial blood pressure without discoverable cause. It is probable, however, that such cases are those of beginning nephritis where the

urine is perfectly normal, as far as chemical examination reveals, but the circulation of some poison in the blood causes a rise of pressure. This is a very interesting group of cases, and more will be said about it later.

Age.

No age is exempt from the lesions of arteriosclerosis if we consider the two groups. However, the disease is seen for the most part in persons past middle life. The relative frequency with which it is found in the different decades depends on so many factors that it is of no value to tabulate them. As has been stated, arteriosclerosis of all types is an involution process that advances with age. Longevity is a question of the integrity of the arterial tissue, and no one can tell what sort of "vital rubber" (Osler) any one of us has. However, many with poor tubing may make such use of it that it will outlast good tubing that is badly treated. Unfortunately we have no way of telling early enough with just what sort of arterial tissue we are starting life.

Sex.

There is no doubt that men are far more prone to arterial disease than women are; all statistics are in accord on this point. This is explained by the greater exposure of men to those conditions of life which tend to produce high tension, and so to produce arteriosclerosis, or vice versa. Arteriosclerosis in women is not often seen until after the fiftieth year. Cases of the most extreme grade of pipe stem arteries are, however, seen in old women, and calcified arteries are not hard to find among the inmates of an old woman's home.

Race.

Some of the most beautiful examples of arteriosclerosis in this country are seen in the negro. Not only is this disease more frequent in the black race, but the age of onset is much earlier than in the Caucasian. The accidents of arteriosclerosis, viz., aneurysm, cerebral hemorrhage, etc., are more common among the negro males. The etiological factors that are most often found in the history are the prevalence of syphilis and hard physical labor.

Occupation.

Certain occupations have a distinct causal relationship to arteriosclerosis; among such are particularly those entailing prolonged muscular exercise, especially if much lifting is necessary. Every one is familiar with the phenomena accompanying the exertion of lifting. The breath is drawn in, the glottis is closed, and the muscles of the chest wall are held rigidly while the exertion lasts. This causes a great increase in blood pressure, and constant repetition of this will produce permanent high tension. In hospitals, the stevedores as a class have marked arteriosclerosis, and, almost without exception, they are comparatively young men. Occupations that are accompanied with prolonged mental strain, such as now occur to the heads of large manufacturing and financial institutions, also predispose to early arterial changes. Psychic activity, especially when it is accompanied by worry, is a potent factor in the production of the increased blood pressure which is the chief factor in producing arterial disease. It has been suggested that sexual continence in high-strung men produces changes in the nervous system which can conceivably lead to the production of high tension and further to arteriosclerosis.

There are, however, men who seem not to be harmed by the constant wear and tear of our modern life. These are the exceptions.

Workers in factories where paint is made and the ingredients hand-mixed, are prone to develop arteriosclerosis early in life. It has been found that the laborers most apt to be victims of lead intoxication are those who are careless in their habits of cleanliness, particularly in regard to the fingernails. The continuous absorption of lead into the system, brings about a condition of hypertension that has its inevitable results.

The fact is that any occupation which entails either the absorption of toxic substances, or prolonged muscular labor, will hasten markedly the onset of arterial disease.

Infectious Diseases.

As more study has been given to the arteries in persons who have died of the acute infectious diseases, more has come to light concerning the effects of the toxins of these diseases on the vessel walls. In the arteries of children who have died of measles, scarlet fever, diphtheria, cerebrospinal meningitis, etc., degenerative changes in the arteries occur, modified only by the length of time that the toxins have acted.

Thayer has shown that the arteries of those who have passed through an attack of moderately severe or severe typhoid fever are as a rule more readily palpable than are the vessels of persons of corresponding years who have never had the disease. Clinically the typhoid toxin appears to cause the early production of arteriosclerosis. The changes in the arteries occur for the most part, and always earlier, in the peripheral arteries, and the media is chiefly

affected. Minute yellowish patches are found on the aorta, carotids, and coronaries. In persons who have passed through an attack of one of the fevers, and have later died from some other cause, regenerative changes are sometimes found to have taken place in the arteries, consisting of an ingrowth of elastic fibers from the intact adventitia to the diseased media.

Syphilis.

This is one of the most important of the etiological factors in the production of arteriosclerosis. Acute aortitis affecting the ascending and transverse portions of the arch of the aorta is very commonly seen, and the irregular, scattered, slightly raised, yellowish-white patches of sclerosis in the arch which are found years after the syphilitic lesion, are considered by some to be very characteristic of syphilis. Mesaortitis is the primary lesion and acts as a *locus minoris resistentiæ* where an aneurysm forms. In fact, it is claimed (Osler) that all aneurysms occurring in persons under thirty years of age are due to syphilitic aortitis. In the late stages of syphilis the arterial lesions may be of a diffuse character.

Chronic Drug Intoxications.

Lead, tobacco, and according to some, tea and coffee, are to be classed as causal factors in the production of arteriosclerosis. Certain it is that all these substances have a tendency to raise the arterial pressure, but whether the drug itself causes first a degeneration, and later hypertension results, or vice versa, is not yet positively known. We have just mentioned that lead particularly has a marked effect in producing arterial lesions. Other drugs as adrenalin, barium chloride, physostigmin, etc., while produ-

cing experimental arteriosclerosis, hardly could produce the disease in man. **Alcohol** has been blamed for much, and as an etiological factor in the production of arteriosclerosis formerly was accorded a first place. More recently much doubt has been thrown on this supposition by the work of Cabot, who showed that the mere drinking of even large quantities of spirits had no effect in producing arterial disease.

This observation has been recently substantiated by Hultgen, who carefully studied clinically 460 cases of chronic alcoholism. He says, "There are no cardiovascular symptoms which might be termed characteristic of chronic alcoholism, unless it be the peculiar fetal qualities of the heart sounds which we know as embryocardia. I find this very frequent among drinkers, but I can offer only a tentative explanation for it, namely, the following: Embryocardia can only occur with low tension blood pressure, and in the absence of renal insufficiency. Hence it might be considered as a useful condition of no pathologic significance at all. That alcohol is a sclerogenic pharmakon and productive of arteriosclerosis with its usual train of symptoms may be a fact, but its demonstration would be difficult and is really not shown by my tabulations. There were cardiovascular changes, such as myocarditis, aortitis, valvular heart disease and arteriosclerosis in chronic alcoholics in 54.3 per cent of 461 cases, but this by no means constitutes a proof of the causal relationship between these lesions and the abuse of liquors. I believe it, nevertheless, to be good reasoning to ascribe the bulk of cardiovascular symptoms to the sclerogenic action of alcohol, while abstaining from an interpretation of its pathogenesis." Just what rôle **tobacco** plays is difficult to say. My own opinion is, that of itself when used in moderation, it has no ill effects. However, as tobacco is a drug that raises markedly

the blood pressure, excessive use must be held responsible for the production of arteriosclerosis. It is difficult to separate its effects from those produced by eating and drinking.

Over-eating.

There can be no doubt but that the constant overloading of the stomach with rich or difficultly digestible food is responsible for a large number of cases of arteriosclerosis. Every one must have noted the increase in force and volume of the heart beat after the ingestion of a large meal. The constant repetition of such processes conceivably can lead to damage to the vessel walls through hypertension.

In the metabolism of food in the intestines there are substances produced which are poisonous when absorbed directly into the circulation. Ordinarily these substances are rendered harmless either before absorption or are detoxicated in the liver to harmless substances. It is conceivable that a constant overproduction of such poisons would eventually damage the defensive mechanism of the body to such an extent that some of the poisons would circulate in the blood. An expression of a surplus of one, at least, of these decomposition products is the appearance of indican in the urine. It is not believed that indicanuria has the importance attached to it which some authors would have us believe. It is found too often and in too many varying conditions, nevertheless it undoubtedly does reveal the presence of perverted metabolism.

In how far the toxins absorbed from the intestinal tract are responsible for the production of arterial disease, it is not possible to say. Some observers lay great stress on this factor as a cause of arteriosclerosis. The author believes that the rôle played by the absorption of products of

perverted intestinal metabolism is an important one. The primary change is an increased tension in the arterioles which later leads to thickening of the coats of the vessels and to the other consequences of arterial disease. A vicious circle is thus established which has a tendency to become progressively worse.

Mental Strain.

More and more does one become impressed with the fact that patients with arteriosclerosis are very often those who take life too seriously and either from ambition or from an exalted sense of duty lead especially strenuous lives. Not always are these persons addicted to drug or liquor habit. Many are rather abstemious in their habits. It is not so often that we see as a victim of arteriosclerosis, the carefree person who laughs his way through life without worrying about the morrow. He is not so prone to arteriosclerosis. Worry is a far more potent cause of breakdown than actual manual work. It is the rule to find thickened arteries among neurasthenics. This may be only part of a generalized degeneration of all tissue in the body. The blood pressure in such persons is usually low. So many men of our better class live under a continuous mental strain in the business world. The increase in arteriosclerosis cases is real, not apparent. The intense mental strain seems to cause a marked increase in blood pressure (for short periods of mental effort this has been proved) over a period of time sufficient to cause permanent changes in the vessel walls. The same sequence of events repeats itself; high tension, arterial strain, compensatory thickening, hypertrophied heart, etc.

Certainly the character of the arterial tissue has much to

do with the determination of degenerative changes which may result from the action of one or more of the etiological factors.

Muscular Overwork.

This is to be reckoned with as an etiological factor. One sees it especially among the laboring class in both whites and negroes. Possibly other factors, as alcohol and coarse heavy food, contribute to the early arterial degeneration. Hypertrophy of the heart occurs in athletes, and statistics gathered among the oarsmen especially, show a relatively high mortality at the different decades traceable to the high tension produced while in training. This question deserves more consideration than has been accorded it.

Renal Disease.

Chronic disease of the kidneys is one of the most certain producers of hypertension; in fact, some maintain that high tension, even without demonstrable kidney lesions, as revealed by careful urine examinations, is a valuable sign pointing to chronic nephritis. Just what causes the increase in blood pressure sometimes to over 270 mm. of Hg., is not definitely known. It seems most probable that it is some poison elaborated by the diseased kidneys and absorbed into the general circulation. There it acts primarily on the musculature of the arterioles causing tonic contraction and an increase of work on the part of the heart to force the blood through narrowed channels. One fact is certain. We see patients in coma due to renal disease with blood pressure much over 200 mm. of Hg. As these cases clear up, the pressure falls and should they seemingly recover, the recovery is accompanied with a marked decrease in blood pressure, finally reaching the normal for the indi-

vidual. Moreover, in the course of a severe acute or subacute nephritis, hypertension is associated with headache, partial or total blindness, and drowsiness. When the pressure is reduced, all these symptoms disappear.

There is also the chronically shrunken and scarred kidney known pathologically as the arteriosclerotic kidney. It is probable that there are two groups of cases which we may designate: (1) primary; (2) secondary. In the primary group the kidney disease antedates the sclerosis of the arteries, and the sclerosis is most probably dependent on the constant high tension. We know that prolonged hypertension will produce severe forms of arteriosclerosis. The arterial disease in this group is caused by the renal disease.

In the second group the kidney changes are apparently due to the general arteriosclerosis which, affecting the kidney vessels, causes changes leading to atrophy and subsequent fibrous tissue ingrowth of scattered areas. These cases are not necessarily associated with hypertension; on the contrary there is more apt to be hypotension. Where the first group occurs for the most part in young and active middle-aged people, the second group is the result of involutionary processes which accompany advanced age.

We have learned that, however careful analysis of the urine may be, we cannot be sure of the pathological state of the kidney which secretes the urine. Too often so-called normal urine will be secreted by a badly diseased kidney, whereas a urine which contains considerable albumen and many casts may be secreted by a kidney almost perfectly healthy, the lesions being only of a transient and trivial nature.

The diagnosis of a case does not consist in the determination of any one more or less obvious point, or even in the loose correlation of several factors. Diagnosis with some

is a rapid mental process, with others a slow weighing of all the facts known and balancing them against one another. The rapid method is to be preferred but it can only be arrived at by long training with the slow, careful method.

CHAPTER V.

THE PHYSICAL EXAMINATION OF THE HEART AND ARTERIES.

Heart Boundaries.

In order to be able to estimate the departures from normal in the boundaries of the heart, it is essential that there be a definite appreciation of the boundaries of the normal heart in relation to the chest wall.

It is frequently stated that the right limit of cardiac dullness is normally, in the adult, just at the right border of the sternum. This is not strictly accurate. Careful dissections at the autopsy table show that the border of the right auricle is from one to one and a half and even two centimeters from the edge of the sternum at the level of the third interspace and on the living subject this can be also demonstrated.

Again there is a term used in defining the apex known as the point of maximum impulse. As this does not always coincide with the apex beat and with the outer lower left border of the heart, it would be better to use the term apex beat.

Normally, then, the cardiac dullness, the so-called relative cardiac dullness, begins above at the upper border of the third intercostal cartilage, as a rule, and taking a somewhat curved line with the concavity inward, descends to the fifth interspace or beneath the fifth rib from 9 to 10 cm. from a line drawn through the center of the sternum parallel to its length, the mid-sternal line. This seems to me to be a bet-

ter method of recording the size of the heart than by the lines commonly used, viz: the nipple, or mid-clavicular, or parasternal line. Below, the cardiac dulness is merged into the tympany from the stomach and the dulness from the liver. At the sixth right costosternal articulation there is a sharp turn upwards forming at that point with the liver the cardiohepatic angle. At the fourth right cartilage or the third interspace, the dulness is from one to two centimeters from the edge of the sternum. We have then a somewhat pear-shaped area or triangular area with the apex at the apex of the heart. The so-called absolute cardiac dulness does not appear to me to be of any great significance. In reality it is the limit of lung resonance and may be greater or less, not so much on account of variations in the size of the heart, as of variations in size of the lungs and shape of the chest wall.

The really crucial question which should always be asked is, Is the heart enlarged or decreased in size? The position of the apex beat alone can not determine this, nor can the limit to the right of the sternum. The distance between these two points and the depth of the dulness at a distance of 5 cm. from the midsternal line on the left side, will give the size of the heart as nearly as can be obtained in the living subject. A series of measurements in normal adults average 13 to 14 cm. and 9 to 10 cm. respectively. For women they are about 1 cm. less in each direction.

The elaborate mechanism known as the orthodiagraph is probably the best means of determining the actual limits of the heart, but few men have such an expensive instrument, and, moreover, at the bedside such an instrument could not be used. From comparative measurements I concur in the belief of those who affirm that careful percussion will furnish equally as accurate limits.

The first step in making an examination of the heart is to

expose the patient's chest in a good light, and, sitting at his right side, carefully inspect the chest. The position of the apex beat, heaving, bulging, retraction of interspaces, etc., can easily be seen if visible. After careful inspection has given all the data which it is possible to obtain, one next lays the palm of the hand over the heart and attempts to palpate the apex beat. The thrust of the apex in a hypertrophied heart can readily be felt, and one can feel whether the heart is regular, irregular, intermittent, or has other change in rhythm. The shock of the closing valves, particularly the aortic, can be felt, and that, together with the forcible apical impulse, are very definite signs of hypertrophy and hypertension. Thrills may also be felt and can be timed in relation to the heart cycle.

Percussion.

It is to percussion that we next proceed, and for the data in regard to the size of the heart, it is, for our purpose, the most valuable of all the physical methods of heart examination.

First and foremost we wish by percussion to learn the actual size of the heart, in other words what is ordinarily called the relative cardiac dulness. With the absolute dulness we are not concerned. That irregular area represents, as has been said, actually the **limits of lung resonance.** The heart may or may not be covered with lung; there may or may not be the incisura cardiaca. What I wish to insist upon is that the size of the area of absolute dulness can give us no data in regard to the size of the heart. What we must endeavor to learn is the actual size of the heart as nearly as our crude means will permit.

Light, very light, almost inaudible percussion, what Goldscheider called "Schwellungsperkussion," must be prac-

ticed. Use the middle finger of the right (left) hand as the hammer and the last joint of the middle finger of the left (right) hand pressed firmly against the chest, as plexímeter. I believe it is better to place the plexímeter finger parallel to the boundary to be limited although some place the finger perpendicularly, that is, pointing toward the boundary. Now and then it helps to bend the plexímeter finger at the second joint, hold it perpendicularly to the chest wall, and strike the joint directly in line of the finger. This in my hands has been of great assistance in percussing the limits of the heart dulness. Pottenger's "light touch palpation" is a modification of the light palpation and, to my mind, has no very special advantages. Auscultatory percussion is of great value at times. The bell of the stethoscope is placed over the portion of heart uncovered by lung (should such be the case), and with this point as a center the chest is lightly and quickly tapped along radii converging toward the stethoscope. One soon learns to recognize the change of pitch as the tapping reaches the border of the heart. It is well to use all methods, especially in difficult cases, and to compare the results. Personally I have found that by light percussion I can limit with much accuracy the upper, right, and left borders of the heart.

There is much to be gained by using light percussion. Strong blows set in vibration not only the underlying structures, but also more or less of the chest wall. We wish to avoid this source of error, we do not wish to differentiate by pitch alone. Finally one's plexímeter finger becomes, after long practice, so sensitive to changes in the resonance of structures lying below it, that there is actual feeling of impairment to the slightest degree. This delicate touch is what we should endeavor to cultivate.

It is at times of advantage to use immediate percussion. This is done by bending the fingers of the striking hand,

bringing the tips in a line and striking the chest lightly with the four fingers as one finger. Some find it easier to percuss the dulness due to the heart in this way than by mediate percussion.

The little hammer and hard rubber, celluloid, bone, or ivory pleximeter does not seem to me to be nearly as good as the fingers. Moreover, one always has his hands, but may forget his hammer and pleximeter.

Auscultation.

In auscultating the heart I prefer the binaural stethoscope of the Ford pattern. The recent substitution of an aluminium bell for the hard rubber bell is an improvement. Personally I do not favor the phonendoscope or any of the new patent non-roaring instruments now for sale by urgent instrument makers. The phonendoscope has its uses, for example in auscultating the back when a patient is lying in bed or in listening to the heart sounds when a patient is under an anesthetic; but for differentiating the murmurs and for heart diagnosis, I much prefer the regular bell stethoscope.

In arteriosclerosis the two places over which it is important to listen are the apex and the second right cartilage, the aortic area. Over the former, one gains data in regard to the strength of the heart as indicated by the first sound, over the latter point, one learns of the tension in the aorta by the character of the sound produced when the aortic valves close.

The hypertrophy of the heart in arteriosclerosis is invariably due to the enlargement and thickening of the left ventricle. From the nature of the position which the heart assumes in the thorax, this enlargement is downward and to the left. The apex beat will therefore be found in the

fifth or sixth interspace, and definitely at an increased distance from the midsternal line. As stated above, it is most important that this distance be accurately measured and put down in the notes of the case for future reference. No satisfactory prognosis can be given unless this is done, for the gradual increase or the decrease under treatment in the size of the heart can thus be definitely known, and, knowing the other factors, a prognosis may be given which will be of some value to the patient.

The Examination of the Arteries.

It is exceedingly difficult at times to affirm definitely that an artery, the radial for example, is actually sclerosed. Much depends on the sensitiveness of the fingers of him who palpates, and much upon the relation of the palpated artery to the surrounding, chiefly underlying, structures. In the examination of arteries it is well to inspect the body for the pulsations caused by them. Frequently an exceedingly tortuous artery, such as the brachial, may be seen throughout its whole extent and yet the radial appear little, if any, thickened by palpation. Again the artery of a pulse of high tension which is small in size but full between the beats, may not be as sclerosed as one which collapses and feels much softer. It is difficult to obtain accurate data in regard to the tension in an artery by feeling it with the fingers of one hand. One should use both hands. With the middle finger of the right (left) hand the artery is compressed peripherally, that is, nearest the wrist. The blood is then pressed out of the artery with the middle finger of the left (right) hand, so as to obliterate completely the pulse wave and the two or three inches between the middle fingers are felt with the index fingers. By holding the finger firmly on the artery near the wrist so as to block any wave that

may come through the palmar arch by anastomosis with the ulnar artery and by releasing pressure on the proximal middle finger, some idea may be had of the degree of pulse tension. However, no amount of practice can more than approximate the tension and when one is surest that he can tell how many millimeters of pressure there is, he is apt to be farthest wrong when he checks his guess with the sphygmomanometer.

Much may be learned from carefully palpating the peripheral arteries, and, as a rule, the sclerosis of these arteries means general arteriosclerosis, although there are many exceptions to this.

A more recent method, and one which in the author's hands has been found to be valuable, is that proposed by Wertheim-Salomonson who palpates the artery not with the ball of the finger but with the fingernail. The finger is held so that the nail is perpendicular to the surface of the skin and the artery is felt with the end of the nail. The sensation is perceived at the root and makes use of all the sensitive nerve endings there. In this way it is possible to feel the arterial wall distinctly, and a little practice will enable one to determine whether or not the vessel wall is thickened. It is also possible to determine with a considerable degree of accuracy the diameter of the artery and the size of the wall when the current is cut off by pressure on the proximal side of the artery. It is best to have a firm background when this "fingernail" palpation is used. This may be obtained by palpating the radial artery against the lower end of the radius.

Probably the best method of palpating the arteries, especially the radial, to determine the degree of sclerosis and thickening, is to use the tip of the finger and roll it carefully over the artery. The tip of the finger is exceedingly sensitive and, moreover, it is a firmer palpating surface than

the ball, thus enabling one to appreciate degrees of sclerosis which could not be differentiated by palpation with the soft yielding ball. This finger tip palpation is well illustrated in the figures here shown. (Figs. 27 and 28.)

Estimation of Blood Pressure.

It must be borne in mind at the outset that arteriosclerosis and high blood pressure are not always associated. As a matter of fact in the severest grades of senile arteri-

Fig. 27.—A method of finger-tip palpation of the radial artery. (Graves.)

osclerosis the blood pressure is usually below the normal for the individual's years. However, as high tension is a frequent factor in the production of arterial thickening, blood pressure readings are of importance.

Instruments.

A number of instruments have been devised to measure the blood pressure in man since V. Basch made the first one in 1887. Modifications have been made by Riva-Rocci,

Stanton, Cook, Janeway, Erlanger, Hirschfelder, and others. (V. Chap. iii.)

Some prefer the tonometer devised by Gaertner or one of the modifications of which many are sold in Germany. This is an excellent means of measuring the systolic pressure.

In using the sphygmomanometer with the 12 cm. arm band, it is important that the arm band be fitted smoothly over the upper arm and that the side next the axilla be drawn snugly.

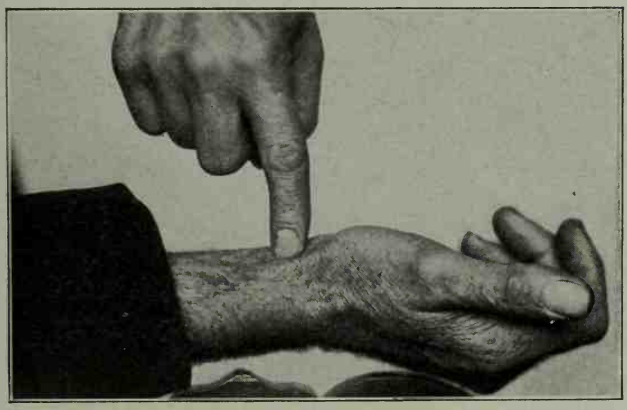

Fig. 28.—Another method of finger-tip palpation of the radial artery. (Graves.)

The lower side should be snug but not so tightly drawn. One feels the pulse at the wrist with the fingers of one hand, and with the air-bag forces air into the arm piece beyond the point where the pulsation at the wrist ceases to be felt.

The valve is then closed and gradually opened so that the mercury in the manometer falls one to two millimeters at every heart beat. Before the pulse wave can be felt at the wrist the mercury column is seen to oscillate very slightly.

The point at which the mercury makes a sudden increase in excursion should correspond with the first sensation of pulsation in the radial artery at the wrist. This point read

off on the scale opposite the mercury column registers the systolic pressure in millimeters of mercury. The mercury is allowed to fall still lower and the excursion becomes gradually larger until a point is reached about 40–45 mm. below the systolic pressure where the mercury column again suddenly makes its largest excursion. This is the diastolic pressure and corresponds to the greatest pulse wave felt at the wrist. The difference between the systolic and the diastolic pressures is the pulse pressure which measures the force with which the blood is sent through the vascular system during the diastole of the heart. It is essential that several readings be made, at least four, and the average taken. After some practice the four readings should not vary more than 5 mm. Hg.

Auscultation.

Another method of determining the systolic and diastolic pressures in the brachial artery is the auscultatory method [1] first described by Korotkow (v. chap. iii).

Practically one applies the 12–14 cm. arm band of the blood pressure instrument in the usual way and compresses the bulb until the mercury registers above the maximum systolic pressure. The bell of the stethoscope is then placed at the inner side of the arm just above the elbow and 2–4 cm. below the cuff, and the compression released gradually. The first sharp sound heard is synchronous with the sudden excursion of the mercury and the figure is read off on the scale alongside of the manometer. This is the systolic pressure. The pressure is still further eased until the point is reached at which no sound is heard. This reading on the manometer scale at this point corresponds to the

[1] For a discussion of the theories of the sounds produced see J. C. Gittings, Arch. Int. Med., Vol. VI, 1910, p. 196.

diastolic pressure. It has been said within that the systolic maximum pressure by this method and by the palpation method correspond fairly well, but the minimal pressure is from 13.2 mm. to 24 mm. lower by the auscultatory method. This means, of course, that the pulse pressure is from nearly 60 to 70 mm. instead of the usual 40 to 45 mm. as given in most textbooks.

On the whole the auscultatory blood pressure determinations are to be preferred, for the readings in the hands of one not thoroughly experienced in palpating radial arteries for blood pressure will be less accurate. The physician who uses the blood pressure instrument only now and then (and this applies especially to the specialists), will undoubtedly think much more highly of the value of blood pressure determinations if they adhere to the auscultatory method.

Palpation.

Hoover has called attention to the direct palpation of the femoral artery just below Poupart's ligament as a more accurate index of the pressure in the aorta than the palpation of the radial artery. Possibly one can obtain a more accurate estimate of the blood pressure in this way. This, however, is open to dispute. To estimate the blood pressure by palpating the radial artery is most deceptive. In about seventy-five per cent of cases one can tell fairly well whether the pressure is abnormally high or abnormally low. Small variations are impossible to determine. Unquestionably it is most advantageous to get into the habit of palpating the femoral artery and checking the result with the sphygmomanometer so that the fingers may be trained to appreciate as accurately as possible changes of pressure.

It may be that one day when the instrument is needed it

is not at hand. A well-trained touch then becomes a great asset.

Precautions When Estimating Blood Pressure.

There are certain precautions which must be strictly observed when deductions are drawn from the manometer readings. The psychic factor must be reckoned with. Any emotion may cause marked variations in the pressure. Excitement and anger are especial sources of error. Even the slight excitement arising from taking the first blood pressure on a nervous patient especially is apt to give false values. Usually the readings must be taken many times at the first sitting and the first few may have to be set aside. Worry is a potent factor in raising the pressure. A walk to the physician's office, especially if rapid, has its effect.

The position of the patient when the blood pressure is taken is important. Usually in the office the pressure is taken when the patient sits in a chair. He should assume a relaxed, comfortable attitude. The readings should be made at the same time of day and at the same interval between meals. The pressure in both arms should be measured and comparisons should be made only between readings on the same arm. These precautions may seem useless and even somewhat trivial, and the conditions difficult to control. But unless they are carefully observed the readings will be false, no comparisons can be drawn between the readings on different days, and the instrument will most probably be blamed. I have known this to happen so often that I cannot emphasize too strongly the importance of controlling all the essential conditions which go to make accurate work.

Value of Blood Pressure.

The value of the estimation of the blood pressure is not sufficiently recognized in spite of the emphasis which has been laid upon it in the past few years. There are some who have attempted to use the instruments and have discarded them because they obtained such variable readings that the instruments seemed of little value. But before throwing away any instrument which has been well recommended by the best clinicians and laboratory workers throughout the world, it is well to ask one's self whether the instrument only is at fault. If others have found it of value, then the fault is not in the instrument, but most probably in him who uses the instrument wrongly.

CHAPTER VI.

SYMPTOMS AND PHYSICAL SIGNS.

General.

As involution processes are physiological, as has been described (vide infra), arteriosclerosis may assume an advanced grade and run its course devoid of symptoms referable to diseased arteries. It is doubtful if the sclerosis itself could produce symptoms, except in cases later to be described, were it not that the organs supplied by the diseased arteries suffer from an insufficient blood supply and the symptoms then become a part of the symptom complex of any or all the affected organs.

There are cases, however, in comparatively young persons where a combination of certain ill-defined symptoms gives a clue to the underlying pathological processes. These symptoms of early arteriosclerosis are the result of slight and variable disturbances in the circulation of the various organs. Normally there are frequent changes in the blood pressure in the organs but the vasomotor control of normal elastic vessels is so perfect that no symptoms are noted by the individual. When the arteries are sclerosed, they are less elastic and the blood supply is, therefore, less easily regulated. At times symptoms occur only after effort. The patient may tire more readily than he should for a given amount of mental or bodily exercise; he is weary and depressed, and occasionally there is noted an unusual intolerance of alcohol or tobacco. Vertigo is common, especially on rising in the morning or in suddenly changing

from a sitting to a standing position. Some complain of constant roaring or ringing in the ears. There may be dull headache that the accurate fitting of glasses does not alleviate. Unusual irritability or somnolency with a disinclination to commence a new task may be present. Sometimes the effort of concentrating the attention is sufficient to increase the headache. This has been called "the sign of the painful thought." Numbness and tingling in the hands, feet, arms, or legs are also complained of, and neuralgias, not following the course of the nerves but of the arteries, also occur. It is important to remember that the train of symptoms resembling neurasthenia in a person over forty-five years old may be due to incipient arteriosclerosis. This tardy neurasthenia frequently accompanies cancer, tuberculosis, diabetes and incipient general paralysis, as well as incipient arteriosclerosis.

Bleeding from the nose, epistaxis, taking place frequently in a middle-aged person, sometimes is an early symptom. The bleeding may be profuse but is rarely so large as to be positively harmful. In fact, it may do much good in relieving tension. Slight edema of the ankles and legs is seen. Dyspnea on slight exertion is not uncommon. Dyspeptic symptoms are not infrequent, pyrosis (heartburn), a feeling of fulness after meals with belching or a feeling of weight in the epigastrium. The dyspeptic symptoms may be so marked that one might almost speak of a variety of arteriosclerosis, the dyspeptic type. For quite a while before any symptoms that would definitely fix the case as one of undoubted arteriosclerosis, the patient complains that foods which previously were digested with no difficulty now give him gastric distress. The examination of the stomach contents of a patient presenting gastric symptoms reveals usually a subacidity. The total acidity measured after the Ewald test meal may be only 20 and the free HCl may be

absent. Attention has been called to an unnatural pallor of the face in early arteriosclerosis. Progressive emaciation is sometimes seen in cases of arteriosclerosis and may be the only symptom of which the patient complains.

Hypertension.

Not all cases of arteriosclerosis are accompanied by increased arterial tension. As has been stated in a previous chapter, the blood pressure in the arterial system depends chiefly on two factors, viz.: the degree of peripheral (capillary) resistance, and the force of the ventricular contraction. The highest arterial pressures recorded with the sphygmomanometer occur not in pure arteriosclerosis but in cases where there is concomitant chronic interstitial disease of the kidneys. When this is found there is always arteriosclerosis more or less marked. In cases where the arteries are so sclerosed that they feel like pipe stems there may be an actual decrease in the blood pressure. Hence the clinical measuring of the pressure in the brachial artery alone is not sufficient for a diagnosis of arteriosclerosis. A persistent high blood pressure even with normal urinary findings is not a sign of arteriosclerosis but of incipient chronic nephritis. The high tension later will lead to the production of sclerosis of the arteries but in these cases the kidney is primarily at fault.

The impression must not be gained that hypertension in itself always constitutes a disease or even a symptom of disease. Hypertension itself is practically always a compensatory process. That is to say, it is the attempt on the part of the body to equalize the distribution of blood in the body when there is some poison causing constriction of the small arteries. In this sense hypertension is not only essential but actually life-saving. A heart which is so diseased that

it can not respond to the call for increased action by hypertrophy of its fibers, would shortly wear out. The very fact that the heart becomes enlarged and the tension in the arteries becomes high, indicates that in such a heart there was great reserve power. But while hypertension is largely an effort at adjustment among the various parts of the circulation, it nevertheless tends to increase, provided the cause or causes which produced it act continuously. Moreover, as has been said (Ch. ii), the arterioles do not respond to increased work on the part of the heart by expanding, but by contracting. A vicious circle is thus maintained which eventually must lead to serious consequences.

Hypertension is then, if anything, only a symptom which may or may not demand treatment. That hypertension leads to the production of sclerosis of the arteries has been repeatedly affirmed here. In certain cases it is good and should not be experimented with. In other cases it is bad and some treatment to reduce the tension must be tried. The main point is to regard hypertension as one regards a compensated heart lesion.

The Heart.

When the arterial tree becomes narrowed and the resistance offered to the flow of blood thereby is increased, more muscular work is required of the left ventricle and according to the general laws which govern muscles the ventricle hypertrophies. There is an actual increase in number of fibers as well as an increase in the size of the individual fibers. Some of the best examples of simple hypertrophy of the left ventricle are found under such circumstances. The chambers as a rule do not dilate until the resistance becomes greater than the contraction can overcome, when symptoms of broken compensation of the heart take place.

The hypertrophy of the left ventricle brings more of this portion of the heart toward the anterior chest wall. The enlargement is toward the left also, consequently the apex beat is found below and to the left of its usual site, even an inch or more beyond the nipple line. The impulse is heaving, pushing the palpating hand forcibly up from the chest wall. The visible area of pulsation may occupy three interspaces and the precordium is seen to heave with every systole. On auscultation the second sound at the aortic cartilage is ringing, clear, and accentuated. Not infrequently, too, the first sound is loud and booming, but has a curious muffled sound that may even be of a murmurish quality. The leaflets of the mitral valve may be the seat of sclerosis, the edges are slightly thickened and do not quite approximate, thus causing a definite murmur with every systole. This murmur may be transmitted out into the axilla and be heard at the inferior angle of the left scapula.

Palpable Arteries.

Not every artery that can be felt is the subject of arteriosclerosis, and, as has been stated, palpable arteries being more or less a condition of advancing years, judgment as to whether the artery is pathologically or physiologically thickened may be a matter of individual opinion. A radial artery that lies close to the lower end of the radius and can actually be seen to pulsate when the hand is held slightly extended on the back of the wrist, is easily felt, but must not, therefore, be considered a sclerosed artery. The radial may be so deeply situated in the wrist of a fat subject that it is difficultly palpable. Yet the two cases just described may have arteries of identical structure, there being no more retrogressive changes in the one than in the other. "Experience is fallacious and judgment difficult."

The small, contracted, wiry artery of a chronic nephritic may feel like a pipe stem, but if properly felt the mistake will not be made of considering such an artery an unusually sclerosed one. When the wave is pressed out of such a high tension artery, it is found that what seemed to be a firm sclerosed vessel, was in reality an artery tightly stretched over the column of blood.

Ocular Signs and Symptoms.

It would not exaggerate too much to say that the examination of the eye grounds with the ophthalmoscope is the most important aid in the early diagnosis of arteriosclerosis. Long before there are any subjective symptoms, changes can be seen in the blood vessels of the retina which, while not always diagnostic, at least call attention to a beginning chronic disease. As I become more proficient in the use of the ophthalmoscope, I am impressed with the importance of the ocular signs of arterial disease. I would urge practitioners to familiarize themselves with this instrument. The electrically lighted instruments on the market now have so simplified the technic that any physician should be able to see the grosser changes which take place in the arteries and veins of the retina and in the disc. Frequently the ophthalmologist is the first to recognize early arteriosclerosis. In the fundus are seen increased tortuosity of the retinal vessels and their terminal twigs with more or less bending of the vessels at their crossings. The arteries are terminal ones and small patches of retinitis are therefore found. The changes have been divided into (1) suggestive, (2) pathognomonic.

Under (1) are:

(a) Uneven caliber of the vessels,

(b) undue tortuosity,
(c) increased distinctness of the central light streak,
(d) an unusually light color of the breadth of the artery.

Under (2) are:

(a) Changes in size and breadth of the retinal arteries so that they look beaded,
(b) distinct loss of translucency,
(c) alternate contractions and dilatations in the veins,
(d) most important of all, the indentation of the veins by the stiffened arteries.

There is yet another sign which appears to be pathognomonic. The arteries are pale, appear rigid and through the center, parallel to the course, is a rather bright, fine thread-like line. The appearance is known as the "silverwire" artery. It is particularly constant in hypertension where the most beautiful examples are seen.

Moreover, there is the arcus senilis, the fine translucent to opaque circle surrounding the outer portion of the iris. Practically every one with a well-marked arcus senilis has arteriosclerosis, but vice versa not every one with even marked arteriosclerosis has an arcus senilis.

In general, the symptoms are gradual loss of acute vision, and attacks of transient loss of vision. The explanation which has been offered for these phenomena is the contraction in a diseased central artery.

Nervous Symptoms.

The onset of arteriosclerosis is, in the majority of cases, so insidious that certain nervous manifestations due in all probability to disturbances in blood pressure, are present long before the actual sclerosis of the arteries can be felt.

These nervous symptoms are at times the sign posts to show us the way to the accurate diagnosis. There may be gradual increase in irritability of temper, inability to sleep, vertigo even extending to transient attacks of unconsciousness. Loss of memory for details frequently is an early symptom of sclerosis of the cerebral arteries. Nervous indigestion may be present. Various paresthesias as numbness, tingling, a sense of coldness or of heat or burning, a sense of stiffness or even actual stiffness or weakness may occur in the arms and legs, more frequently in the legs. The pain complained of may be due to occlusion of an artery, although evidence for this is lacking. It has been thought by some that the pain in angina pectoris might be due to this cause.

Several curious and interesting diseases which have been thought by some to have arteriosclerosis as a basis are accompanied by pain. Such are erythromelalgia, Raynaud's disease, "dead fingers," and intermittent claudication.

Erb has reported a large series of intermittent limp (claudication) from his private practice. He finds that the large majority of the cases occur in men. The abuse of tobacco was evidently the main etiologic factor in about half of the cases. Repeated exposure to cold and the abuse of alcohol were responsible for most of the other cases. Curiously enough he finds that a history of syphilis was present in only a small proportion of his cases. It is his firm conviction that intermittent limping—which he thinks should be called angiosclerotic dysbasia—is frequently incorrectly diagnosed. It is mistaken for other troubles and treated wrongly. As gangrene may develop this is particularly dangerous. The affection generally develops gradually, although he has seen cases where the onset was rather acute. The partial or complete lack of the pulse in the foot

is the one striking sign, together with the varying behavior of the pulse, its disappearance when the feet are cold and its return after a warm foot bath or under other treatment. Signs of general arteriosclerosis were present in nearly every case. When there is a tendency to the development of intermittent limp he finds that a valuable sign is the manner in which the leg blanches when it is lifted repeatedly while the patient is recumbent and becomes hyperemic later when placed horizontally. In health this change occurs more rapidly.

While arteriosclerosis is usually a disease which is of slow maturation, nevertheless cases are occasionally seen which develop rather rapidly. The peripheral arteries have been noticed to become stiff and hard in as relatively brief a time as two years from the recognized onset of the disease.

Well developed arteriosclerosis shows four pathognomonic signs: (1) hypertrophy of the heart; (2) accentuation of the aortic second sound; (3) palpable thickening of the arteries; and (4) heightened blood pressure. However, it must not be inferred that these signs must be present in order to diagnose arteriosclerosis. It has already been said that a very marked degree of thickening, with even calcification of the palpable arteries, may occur with absolutely no increase of blood pressure, and at autopsy a small flabby heart may be found.

In this connection, the classification of Prof. T. Clifford Allbutt is worthy of extended notice. He divides the causes of arteriosclerosis clinically into three classes: 1. The toxic class—the results of poisons of the most part of extrinsic origin, chiefly those of certain infections. In some of these diseases, the blood pressures, as for example, in syphilis, are ordinarily unaffected; in others, as in lead poisoning,

they are raised. 2. The class he calls hyperpietic,[1] in which an arteriosclerosis is the consequence of tensile strength, of excessive arterial blood pressure persisting for some years. A considerable example of this class is the arteriosclerosis of granular kidney, but in many cases kidney disease is, clinically speaking, absent. 3. The involutionary class, in which the change depends upon a senile, or quasi-senile degradation. This may be no more than wear and tear, a disposition of all or of certain tissues to premature failure—partly atrophic, partly mechanical—under ordinary stresses; or it also may be toxic, a slow poisoning by the "faltering rheums of age." In ordinary cases of this class the blood pressures for the age of the patient, are not excessive. Although the toxins of the specific fevers, notably typhoid, as stated above, and influenza, have been shown to produce arteriosclerosis, this, under favorable circumstances he believes tends to disappear. This has been shown by Wiesel.

As the blood pressure is dependent on the resistance offered by the capillaries and arterioles, there are only two ways in which increased pressure can be brought about; either by rendering the blood more viscous, or by the generation of some poison from the food taken into the body which, acting on the vasomotor center or directly on the finer vessels, arteriolar or capillary, sets up a constriction over any large area, and mainly in the splanchnic area. In regard to the liability to arteriosclerosis, this area stands second only to the aortic and coronary areas. He believes that arteriosclerosis itself has little effect in raising arterial pressure. Many cases are seen in which with extreme arteriosclerosis there was no rise in blood pressure, and some in which pressures have been rising even long before

[1] From πιεσω to squeeze, straiten, oppress or distress. Hyperpiesis, therefore, signifies excessive pressure.

the appearance of arterial disease. Prof. Allbutt also believes that in the hyperpietic cases the arteries undergo a transient thickening, which can be removed if the causes can be reached and overcome.

Clinically speaking, then, hyperpietic arteriosclerosis is not a disease but a mechanical result of disease. If the narrowing of the arterioles is brought about by thickening due to arteriosclerosis, then it would seem *a priori* that such obliteration should cause a rise in pressure. Were the vascular system a mere mechanical set of tubes and a pump, this would happen, but other factors of great importance must be taken into consideration besides the mechanical factors, viz.: chemical and biological factors. Thus, whole parts may be closed and with compensatory dilatation in other parts there would be little or no change in pressure, unless there were hyperpiesis. In established hyperpiesis, we note two conditions in the radial artery: first, a comparatively straight vessel with a small diameter; secondly, a larger, more tortuous vessel, "the large leathery artery." In the cases of the first group, hyperpiesis is often more marked, although not appearing so to the examining finger, than in the second class. In view of the difficulty of estimating by touch alone the amount of hyperpiesis in a contracted hard artery, it is often overlooked until a ruptured vessel in the brain startles us to a realization of our mistake. The "narrow" artery is more dangerous than the tortuous one, for with every change in pressure the passive vessels of the brain must receive blood that under normal conditions would go to other parts of the circulation.

In involutionary sclerosis there is a gradual thickening and tortuosity of the vessel, which, although it may be greater than in the hyperpietic cases, yet is never so dangerous to life. The heart in hyperpiesis hypertrophies and dilates, but such a heart is the result, not an integral part, of the arterial disease.

CHAPTER VII.

SYMPTOMS AND PHYSICAL SIGNS.

Special.

To go into the details of the symptomatology of arteriosclerosis would take us far beyond the scope of this brief volume and defeat the purpose of the book. It would include discussions of many of the diseases of every organ in the body. Only particular groups, which are of chief importance and which visualize the general picture of arteriosclerosis, can here be given.

Although arteriosclerosis is a disease which affects the whole arterial system, it nevertheless never reaches the same grade all over the body. The difference in the structure and functions of the various organs determines to great extent the eventual symptomatology. Endarteritis obliterans of a small sized artery in the liver or leg would lead to no marked symptoms, as the circulation is so rich, that the anastomoses of the blood vessels would soon establish a collateral circulation that would be perfectly competent to sustain the function of the part. Quite different would it be should one of the small arteries of the brain, the lenticulostriate, for example, which supplies the corpus striatum, become the seat of a thrombosis or embolism caused by arteriosclerosis. The arteries of the brain are terminal arteries and the blood supply would be cut off entirely with a resulting anemic necrosis of the part supplied by the artery and a loss of function of the part. What would be of no moment in the leg or arm, might prove even fatal in the brain.

The further symptomatology, therefore, of arteriosclerosis depends entirely on the organ or organs most affected by the interference with the blood supply. The following groups may be recognized:

1. Cardiac.
2. Renal.
3. Abdominal.
4. Cerebral.
5. Spinal.
6. Local vasomotor effects.
7. Pulmonary.

Cardiac.

Most cases of arteriosclerosis sooner or later present symptoms referable to the heart. When the organ is hypertrophied and is already working against an enormous peripheral resistance, a slight excess of work put upon it may cause a dilatation of the chambers with the resulting broken compensation. There is dyspnea on slight exertion, possibly some precordial distress, slight edema of the ankles and lower legs and possibly scanty urine. With proper care, a patient with such symptoms may recover, but the danger of another break in compensation is enhanced. The next attack is more severe. The edema is greater, there may be signs of edema of the lungs, effusions into the serous cavities may occur. The heart shows marked dilatation. There is gallop or canter rhythm and there are loud murmurs at the apex. When a patient is first seen in this stage, it may be quite impossible to state whether or not there is true valvular disease of the heart. The muscle is usually diseased in that there is fibroid degeneration of more or less extensive character. This factor causes the heart to

lose much of its elasticity and increases the tendency to permanent dilatation. Such cases must be watched before one can say that true valvular insufficiency is not present. The fatal termination of such a case is quite like that of true valvular disease. There is increasing dyspnea, increasing anasarca, and the patient usually succumbs to edema of the lungs, drowned in his own secretions.

A very rare complication of the fibroid degeneration of the heart muscle is aneurysm of the heart wall. The apex of the left ventricle is most commonly the site of the aneurysm and rupture occasionally occurs. Such an accident is rapidly fatal. In the arteriosclerotic process which occurs at the root of the aorta, the coronary arteries become involved both at the openings and along the courses of the vessels. A branch or branches or even one artery may become blocked as a result of obliterating endarteritis. The arteries of the heart are terminal vessels and as a rule blocking of them leads to anemic infarcts. These areas become replaced by fibrous tissue which in the gross specimen appears as streaks of whitish or yellowish color in the musculature. Anemic infarcts may not occur. If such is the case, there must be either abnormal anastomotic communications between the otherwise terminal vessels, or the circulation is maintained by means of the vessels of Thebesius. Through arteriosclerosis of the coronary vessels extensive fibrous changes may occur that lead to a myocarditis with its attending symptoms—dyspnea, irregular and intermittent heart, gallop rhythm, edema, etc. One of the most distressing and dangerous results of sclerosis of the coronary arteries and of the root of the aorta is angina pectoris. While in almost every case of angina pectoris there is disease of the coronary arteries, the contrary does not hold true, for most extensive disease, even embolism, of the arteries is frequently found in persons who never

suffered any attacks of pain. This symptom group is more common in males than in females and as a rule occurs only in adult life. "In men under thirty-five syphilitic aortitis is an important factor." (Osler.)

Since the valuable experiments of Erlanger on heart block, considerable attention has been paid to lesions of the Y-shaped bundle of fibers, a bundle arising at the venous orifices in the right auricle and extending to the two ventricles, known also as the auriculo-ventricular bundle of His. Interference with the transmission of impulses through this bundle gives rise to the symptom group known as the Stokes-Adams syndrome, which is characterized by: (a) slow pulse, (b) cerebral attacks—vertigo, syncope, transient apoplectiform and epileptiform seizures, (c) visible auricular impulses in the veins of the neck. Many of the cases which occur are in elderly people the subjects of arteriosclerosis.

So far as we now know all cases of the Stokes-Adams syndrome are caused by heart block which is only another name for disease in the auriculo-ventricular bundle. Of interest here is the fact that besides gummata, ulcers, and other lesions of the bundle, definite arteriosclerotic changes have been found.

"The investigation of a typical case of Stokes-Adams disease has shown that the symptoms of this case are caused by some lesion in the heart which gives rise to the condition now generally termed heart block. Practically all degrees of heart block have been observed, namely, complete heart block and partial block with 4 : 1, 3 : 1, and 2 : 1 rhythm, and occasionally ventricular silences. These stages occurred during recovery.

"Experiments testing the reaction of the heart to various extrinsic influences demonstrate that when the block is complete the ventricles do not respond to influences presumably

of vagus origin, although the auricles still respond normally to such influences, that effects exerted upon the heart presumably through the accelerators still influence the rate of the ventricles as well as that of the auricles.

"When the block is partial the rate of the ventricular contraction varies proportionally with the rate of the auricular contractions but only within certain limits. When these limits are exceeded the block becomes more complete, i. e., a 2:1 rhythm may be changed into a 3:1 rhythm, this into a 4:1 rhythm, and this into complete block, and vice versa.

"The syncopal attacks are, in all probability, directly dependent upon a marked reduction of the ventricular rate. Such reductions of the ventricular rate are always associated with an increase of the auricular rate, and it is believed that the latter is the cause of the former." (Erlanger.)

The epileptiform seizures of the syndrome may be caused by the anemia of the brain resulting from failure of the heart to supply a sufficient quantity of blood.

The apoplectiform attacks are most probably caused by venous congestion when the slowing of the ventricular contractions is not sufficient to cause convulsions, but will just cause complete unconsciousness.

Renal.

Chronic nephritis, hypertension, arteriosclerosis form a most important trinity. Some stoutly affirm that in all cases of high tension there is chronic renal disease. Certainly the very highest blood pressures which we see occur in the chronic forms of kidney disease, interstitial or parenchymatous. The cause is most probably to be sought in some poison which is elaborated in the kidney, is absorbed into the circulation and acts powerfully either on the vaso-

constrictor center as a stimulus, or directly on the musculature of the small arteries all over the body. Usually hypertension is progressive but it may be temporary.

A man, 43 years old, entered the Milwaukee County Hospital in uremic coma. The systolic blood pressure was 280–290 mm. Hg., the diastolic pressure 220 mm. (Janeway instrument). Under treatment his blood pressure gradually became lower, at the same period the albumin and casts gradually disappeared from the urine. In two weeks from admission he seemed perfectly well, there were no albumin or casts found in the urine, and the systolic blood pressure was 136 mm., not a high figure for a muscular man of the laboring class. It must be admitted, however, that such cases are the exception, not the rule.

Patients suffering from the association of chronic nephritis with hypertension die slowly, usually. There is gradual development of anasarca. Headache is frequent and severe. Pains all over the body may occur. The sight may suddenly become dim or may even be lost. Dizziness may be complained of and dyspnea is usually marked. Cyanosis comes on, the pulse becomes weak, irregular or intermittent, heart failure sets in and the patient dies with edema of the lungs.

Another class of renal arteriosclerosis is characterized by a small granular kidney in which fibrous changes of a patchy character have taken place. These scattered areas are the result of obliterating endarteritis of renal arteries here and there with consequent anemia, death of cells, and replacement by fibrous tissue. It occurs as part of a generalized arteriosclerosis in which the whole arterial system is the seat of diffuse (senile) sclerosis. The palpable arteries are usually beaded or even encircled with calcareous deposits and the aorta is the seat of an extensive nodular and ulcerating sclerosis. The heart is usually small, shows

extensive fibrous and fatty changes and possibly the condition known as "brown atrophy"; the blood pressure is low. Such cases do not show any special symptoms. They are anemic, short of breath on exertion, have the appearance and show the signs of senility.

In the first group it is, at times, difficult to say whether the kidney disease or the arterial disease is the most important. From a clinical standpoint the decision is not essential as the end results are much the same in both. However, when actual uremic symptoms dominate the picture, it becomes evident that the disease of the kidney is the chief feature in the causation of the symptoms.

Abdominal or Visceral.

There is an important group of cases to which but little attention has been paid until quite recently. This is the abdominal or visceral type of arteriosclerosis. It has been stated that arteriosclerosis of the splanchnic vessels almost invariably causes high tension. Among others, Janeway has shown that general arteriosclerosis without marked disease of the splanchnic vessels does not cause as a rule increase of blood pressure.

There are cases in which the brunt of the lesion falls upon the abdominal vessels. Such cases have been called "angina abdominalis." It has been suggested (Harlow Brooks) that this type of arteriosclerosis may be determined by constant overloading of the stomach with food, especially rich and spiced food. This causes overwork of the special arteries connected with digestion and so leads to sclerosis of the vessels of the stomach, pancreas, and intestines. Personal habits probably influence to great extent the production of this more or less localized condition.

The organs supplied by the diseased arteries suffer from

changes analogous to those occurring in general or local malnutrition, such as starvation, old age, or local anemias. These changes are atrophy with hemachromatosis (brown atrophy) or fatty infiltration and degeneration. Following the degenerative changes there result connective tissue growth and further limitation of the functionating power of the affected organs.

Pain is a more or less constant symptom of visceral sclerosis. In the early stages there may be only a sense of oppression, of weight, or of actual pressure in the abdomen or pit of the stomach. There may be only recurring attacks of violent abdominal pain accompanied by vomiting. In some cases symptoms of tenderness in the epigastrium, pains in the stomach after eating, vomiting and backache may suggest gastric ulcer. There may be dyspnea and a sense of anguish accompanied with a rapid and feeble pulse. Hematemesis may make the symptom group even more like ulcer of the stomach, and only the course of the disease with the failure of rigid ulcer treatment and the substitution of treatment directed toward relief of the arterial spasm with resulting betterment, enables one to make a diagnosis. The condition may be present for years and the symptoms only epigastric tenderness with dizziness and sweating on lying down after dinner, as in one of Perutz's patients. The attacks are probably due to spasmodic contraction of the sclerosed intestinal vessels with a resulting local rise in blood pressure. The pains are most probably due to the spasm of the intestinal muscles, and some think they are located in the sympathetic and mesenteric plexuses.

This result of arteriosclerosis is not so uncommon, and by keeping this cause of obscure abdominal pain in mind we are now and then enabled to save a patient from operation.

The following case reported by Neusser will serve as a

good example of this so-called angina pectoris gastralgica.

L. G.—47 years old, married, letter carrier, adm. June 12, 1902. The patient had had malaria. At 30 and 40 years he had icterus; suffered much from eructations and when 42 had catarrh of the stomach, which was the beginning of his present illness, and for which he underwent a rigid diet and Carlsbad water cure.

On admission, he complained that when he returned home after work, he suddenly experienced a burning and a feeling of oppression in the stomach, he could not breathe freely, but during the pain had to remain standing and take short, quick breaths. Such an attack lasted about a minute, then he could go on. This sort of attack was repeated every 8 to 14 days. In summer, he had fewer attacks, in fall they became more frequent and especially frequent and severe in winter. Between attacks he felt quite well, could eat anything, had no eructations, no vomiting. Recently the attacks had become more frequent and more severe. Milder attacks began with a drawing pain in the pit of the stomach and a feeling of fulness in the stomach. As soon as the attack ceased there was some belching and then relief was felt. When the attack came on shortly after eating, there followed troublesome vomiting and then relief. Severe attacks began with burning pain in the stomach located deeply, which radiated outward over the chest to the manubrium sterni, with a feeling in the larynx as if the parts were being screwed together, violent pain that extended from the neck over both under jaws to the temples, at the same time there followed sweating and salivation now and again and also radiation of the pain to the teeth.

In especially severe attacks the pain was felt between the shoulders as a band around the chest; deep breathing was impossible. Following the attacks there was great weakness. Actual feelings of impending dissolution the

patient never had, likewise no streaming pains in the left or right shoulders, in the arm or below; no dizziness, no palpitation. The pulse showed no abnormality during the four to fifteen minute attacks.

The exciting causes of the attacks recently were many. Not only walking but also lifting, psychic exertions especially at his work, changes of temperature, e. g., leaving a hot room in winter for the outside cold, would bring on attacks. Especially were attacks brought on easily by taking spicy foods, cheese, wine, whiskey. In the intervals he felt well, had a good appetite, the bowels were regular. He was a moderate drinker and smoker. He had had gonorrhea at 22 years; a soft chancre at 23, no skin eruptions.

P. E. is a well built man, the pupillary reaction is prompt, the patellar reflexes are normal. The mucous membranes are somewhat livid, the skin is slightly icteric. There is visible pulsation at the jugular notch; the arteries are not hard. The sphygmomanometer (Basch) reading is 115; pulse 72; the lungs are normal. The point of maximum impulse of the heart is palpable in 5th interspace, somewhat displaced outward; the dulness reaches on right to sternal border. The second aortic is ringing; after the sound there is a diastolic murmur which is transmitted downwards as far as the xiphoid. Posteriorly to the left from the spine the diastolic murmur and the second ringing tone are plainly heard.

Diagnosis: Sclerosis of the thoracic aorta and insufficiency of the aortic valve. Angina pectoris coronaria.

On July 26th the patient left the hospital much improved.

An autopsy on a case which for many years had attacks of abdominal pain and cramp-like attacks, with high blood pressure and heart hypertrophy, showed extensive sclerosis of the abdominal aorta, superior mesenteric and iliacs.

These vessels were calcified. Hypertrophy of the left ventricle was found. The kidneys were microscopically normal. There were no changes in the ascending aorta but in the descending portion there were scattered nodules and small calcified plaques.

The attacks of pain from which this patient suffered for many years, the hypertrophy of the left ventricle and the increased blood pressure were thought to be directly due to the sclerosis of the abdominal vessels.

Cerebral.

It has been stated that arteriosclerosis is a general disease, yet certain systems of vessels may be affected far more than others, and indeed there may be marked sclerosis at one part of the body and none demonstrable at another part.

In advanced sclerosis there may be one or more of a series of accidents due to embolism, thrombosis, or rupture of the vessels. Such conditions as transient hemiplegia, monoplegia or aphasia may occur. The attacks may come on suddenly and be over in a few minutes; what Allbutt calls "Larval apoplexies." They may last from a few hours up to a day, and are very characteristic. A patient aged 64 years with pipe stem radials and tortuous hard temporals would be lying quietly in bed when suddenly he would stiffen, the eyes would become fixed and the breathing cease. In a few seconds consciousness returned, the patient would shake himself, pass his hand over his brow and ask "Where am I? Oh, yes, that's all right." He had as many as thirty of these attacks in twenty-four hours, none of them lasting over one minute. To just what such attacks are due, it is hard to say. Some have attributed them to spasm of the smaller blood vessels of the brain, but there

have never been demonstrated in the vessels any constrictor fibers.

There is a well recognized form of dementia caused by arteriosclerosis. In general paralysis of the insane and in senile dementia the blood vessels are always diseased. Milder grades of psychic disturbances are accompanied by such symptoms as mental fatigue, persistent headaches, vertigo, memory weakness and fainting. Aphasia, periods of excitement and mental confusion occur in some. Later stages are at times accompanied by inclination to fabulate, loss of judgment, disorientation, narrowing of the external interests, episodes of confusion and hallucinatory delirium.

The hemiplegias, monoplegias and paraplegias may occur again and again and last for one or two days. Unless there has been rupture of the vessels there is complete recovery as a rule.

In persons who have arteriosclerosis with high tension attacks of melancholia are seen. There are at the same time fits of depression, insomnia, irritability, fretfulness, and a generally marked change in disposition. When the tension is reduced by appropriate treatment these symptoms disappear, to recur when the tension again becomes high. On the contrary, attacks of mania are accompanied by low blood pressure. The dizziness and vertigo in cerebral arteriosclerosis are probably due to the stiffness of the vessels which prevents them from following closely the variations of pressure produced by position, and thus, at times, the brain is deprived of blood and a transient anemia occurs.

Arteriosclerosis of the cerebral vessels is always a serious condition. The greatest danger is from rupture of a blood vessel. Another of the dangers is gradual occlusion of the arteries bringing about necrosis with softening of the brain substance. The latter is more apt to be associated

with psychic changes, dementia, etc.; the former, with hemiplegia. It is curious that a small branch of the Sylvian artery, the lenticulo-striate, which supplies the corpus striatum, should be the one which most frequently ruptures. Where the motor fibers from the whole cortex are gathered together in one compact bundle, a very small hemorrhage may and does cause very serious effects. A comparatively large hemorrhage in the silent area of the brain may cause few or no symptoms.

Spinal.

It is conceivable that arteriosclerosis of the vessels of the spinal cord might cause symptoms which would be referred to the areas of the cord where the process was most advanced. The lesions would be scattered and consequently the symptoms might be protean in character.

True epileptic convulsions dependent on arteriosclerotic changes are also seen and are not so uncommon.

This is on the whole a rare condition, much less common than arteriosclerosis of the cerebral vessels. Collins and Zabriskie report the following typical case:

"H., a fireman, 51 years old, was in ordinary good health until toward the end of 1902. At that time he noticed that his legs were growing weak and that they tired easily. Later he complained of a jerking sensation in different parts of the lower extremities and at times of sharp pain, which might last from several minutes to two or three hours. The legs were the seat of a heavy, unwieldy sensation, but there was no numbness or other paresthesia. About the same time he began to have difficulty in holding the urine, a symptom which steadily increased in severity. These symptoms continued until March, 1903, i. e., for three months, then he awakened one morning to find that he was unable to stand or walk, and the sphincters of the bowels

and bladder relaxed. There was no complaint of pain in the back or legs, no difficulty in moving the arms, in swallowing or in speaking. He says he was able to tell when his lower extremities were touched and he could feel the bed and clothes. He was admitted to the City Hospital three weeks later and the following record was made on April 21, 1903.

"The patient was a frail, emaciated man of medium height, who had the appearance of being 55-60 years of age. He was unable to stand or walk. When he was lying, he could flex the thigh and the legs slowly and feebly. There was slight atrophy of the anterior and inner muscles, more of the left than of the right side. The knee jerks and ankle jerks were absent. Irritation of the soles caused quite a typical Babinski phenomenon. The patient had fair strength in the upper extremities, but the arms tired very soon, he said. The grip was moderate and alike in each hand. The motility of the face, head, and neck was not noticeably impaired. There was no difficulty in swallowing, and articulation was not defective. Tactile sensibility was slightly disordered in the lower extremities, although he could feel contact of the finger, the point of a pin, and the like. Sensibility was not so acute as normal; there was a quantitative diminution. Sensory perception was not delayed. There was a distinct zone of slight hyperesthesia about as wide as the hand above the femoral trochanters. Above that, sensibility was normal. There was no discernible impairment of thermal sensibility. No part of the body was particularly tender on pressure. A bedsore existed over the sacrum, and there was excoriation of the genitals from constant dribbling of urine.

"Examination of the chest showed shallow respiratory movements. The heart was regular, weak, there were no murmurs, the second sound was accentuated. Examination

of the abdomen showed that the liver and spleen were palpable, but were not enlarged. The abdominal reflexes, both upper and lower, were sluggish. The patient was slow of speech, likewise apparently of thought. He did not seem to show an adequate interest in his condition, still he was fully oriented and seemed to have a fair memory. His mental reflex was slow. There were indications in the peripheral blood vessels and heart of a moderate degree of general arteriosclerosis. The peripheral vessels, such as the radial, were palpable, the walls thickened, the blood pressure increased.

"The patient did not complain of pain while he was in the hospital, a period of four weeks, nor was there any particular change in the patient's symptoms, subjective and objective, during this time. His mental state remained clear until forty-eight hours before death, when he became sleepy, stuporous, and comatose, dying apparently of cardiac weakness, which had set in simultaneously with the clouding of consciousness."

At autopsy, except for a few small hemorrhages in the posterior horns of the lower dorsal segments on the right side and a similar condition of the left anterior horns, there was nothing noticed. On microscopical examination, there was found wide-spread sclerosis of the vessels of the cord to a marked degree with only slight thickening of the vessels of the brain. There were secondary degenerations of ascending and descending type particularly marked at the ninth dorsal segment. They included portions of all the tracts, the pyramidal tract as well. The symptoms in brief were: (1) weakness and easily induced fatigue of the legs; (2) peculiar sensations in the lower extremities, described as jerky, numbness, heaviness, and occasionally sharp pain; (3) progressive incontinence of urine; (4) progressive paraplegia.

Since one of the chief manifestations of syphilis is sclerosis of the arteries, neurological cases characterized by irregular symptoms and signs which cannot be placed in any of the definite system disease groups, are possibly due to irregularly scattered areas of sclerosis throughout the spinal cord caused by obliterating arteritis. Such cases are not so very uncommon. Several have come under my observation. Further studies of the spinal cords of these cases at autopsy are necessary before a final opinion can be given as to their dependence on arteriosclerosis of the spinal vessels.

Local or Peripheral.

When the arteriosclerosis in the peripheral arteries reaches a stage where endarteritis obliterans supervenes, there is usually no chance for a compensatory or collateral circulation to be established. The area supplied by the vessel undergoes dry gangrene. A portion of a toe or finger or a whole foot or hand may shrivel up. It is more common to see the spontaneous amputation take place in the lower extremities. The same effect may be produced by the plugging of a vessel with a thrombus. There may be much pain connected with the sudden blocking, whereas the gradual obliteration of the blood supply of a toe or foot is not as a rule at all painful. The condition is at times revealed more or less accidentally when a patient injures his toe or foot and discovers that there is no sensation in the part and that the wound instead of healing is inclined to grow larger.

Other interesting vasomotor phenomena are frequently connected with arteriosclerosis. Such a one is the curious condition known as Raynaud's disease, a vascular disorder which is divided into three grades of intensity: (1) local syncope, (2) local asphyxia, (3) local or symmetrical gangrene. This is not the place to describe this condition ex-

cept to say that the condition called "dead fingers" is the most characteristic feature of the first stage. Chilblains represent the mildest grade of the second stage. The parts are intensely congested and there may be excruciating pain. Any one who has ever had chilblains knows how painful they can be. The general health is not impaired as a rule, although the attacks are apt to come on when the person is run down. The third stage may vary from a very mild grade, with only small necrotic areas at the tips of the fingers, to extensive multiple gangrene.

Another and very rare condition in which chronic endarteritis was the only constant finding is the disease described by S. Weir Mitchell and called by him erythromelalgia (red neuralgia). This is "A chronic disease in which a part or parts—usually one or more extremities—suffer with pain, flushing, and local fever, made far worse if the parts hang down." (Weir Mitchell.)

Probably the most frequently seen result of arteriosclerosis in the leg arteries is the remarkable condition, first described by Charcot, known as intermittent claudication. Persons the subject of this disease are able to walk if they go slowly. If, however, any attempt be made to hurry the step, there results total disability accompanied at times by considerable cramp-like pain. The condition is much more prone to occur in men than in women, and Hebrews seem more frequently affected. The cause is most probably to be sought in the anemia which results from the narrowing of the channels through which the blood reaches the part. The stiff, much narrowed arteries allow sufficient blood to pass along for the nutrition of the part at rest or in quiet motion. Just as soon as more violent exercise is taken, calling for more blood, an ischemia of the part supervenes, for the stiff vessels cannot accommodate themselves to changes in the necessary vascularity of the part. A rest

brings about a gradual return of blood and the function of the part is restored. Pulsation may be totally absent in the dorsal arteries of the feet and when the legs are allowed to hang down there is apt to be deep congestion.

In this connection a curious case reported by Parkes Weber will not be out of place. The patient, a male, aged 42 years, complained of cramp-like pains in the sole of the left foot and calf of the leg occurring after walking for a few minutes and obliging him to rest frequently. When the legs were allowed to hang over the side of the bed, the distal portion of the left foot became red and congested looking. No pulsation could be felt in the dorsal artery of the left foot or in the posterior tibial artery. There was no evidence of cardiovascular or other disease. An ulcer on the little toe had slowly healed, but cramp-like muscular pains still occurred on walking. The disease had lasted about five years without the appearance of gangrene.

Weber calls this case one of arteritis obliterans with intermittent claudication.

Pulmonary Artery.

In the symptomatology of sclerosis of the pulmonary artery the clinical signs and symptoms are mostly referable to the obliterating endarteritis of the smaller vessels, while the physical signs are more apt to reveal the involvement of the main trunk. A history of severe infection in the past is frequent, especially smallpox, and accompanying aortic sclerosis with insufficiency of the mitral valve or stenosis of this valve is the rule. Striking cyanosis is an early symptom, while there is little if any dyspnea and edema. Intermittent dyspragia is common. There seems to be no tendency to clubbed fingers. Repeated hemorrhages from the lungs without the formation of infarcts may occur.

There is usually an area of dulness at the upper left margin of the sternum and nearby parts, sensitive to pressure and to percussion, and the heart dulness extends unusually far towards the right. The diagnosis of the right ventricular hypertrophy may be substantiated by a fluorscopic examination.

CHAPTER VIII.

DIAGNOSIS.

Early Diagnosis.

Arteriosclerosis is essentially a disease of middle life and old age. It is not unusual, however, to find evidences of the disease in persons in the third decade and even in the second decade. Hereditary influences play a most important rôle, syphilis and the abuse of alcohol in the family history are particularly momentous. The recognition of the early changes in the arteries among young persons depends largely upon how carefully these changes are looked for. The difference in the point of view of one man who finds many cases in the comparatively young, and another man who rarely finds such changes early in life, at times, depends upon the acuity of perception and observation and not upon the fact that one man has had a series of unusually young arteriosclerotic subjects. The diagnosis of arteriosclerosis may be so easily made that the tyro could not fail to make it. It is, however, the purpose of this volume to lay stress on the earliest possible diagnosis and, if possible, to point out how the diagnosis may be arrived at. It is obviously much to the advantage of the patient to know that certain changes are beginning in his arteries, which, if allowed to go on, will inevitably lead to one or more of the symptom groups described in the preceding chapters.

The combination of (1) hypertrophied heart, (2) increased blood pressure, (3) palpable arteries, and (4)

ringing, accentuated second sound at the aortic cartilage is, in reality, the picture of advanced arteriosclerosis. If the individual is in good condition much may be done by judicious advice and treatment to ward off complications and prolong life with a considerable degree of comfort. But we should not wait until such signs are found before making a diagnosis and instituting treatment. As in all forms of chronic disease the early diagnosis is all important.

The history of the case is the first essential. Often a careful inquiry into the personal habits of a patient, with the record of all the preceding infectious diseases will give us valuable information and may be the means of directing the attention at once to the possible true condition. Particularly must we inquire into the family history of gout and rheumatism. An individual who comes of gouty stock is certainly more prone to arterial degeneration than one who can show a healthy heredity. Alcoholism in the family also is of importance because of the fact that the children of alcoholics start in life with a poor quality of tissue, and conditions that would not affect a man from healthy stock might cause early degeneration of arterial tissue in one of bad ancestry.

What infectious diseases has the patient had? Even the exanthemata may cause degenerations in the arteries, but, as has been shown, such lesions probably heal completely with no resulting damage to the vessel. Should the patient have passed through a long siege of typhoid fever the problem is quite different. Here (vide supra) (Thayer), the palpable arteries do appear to be sclerosed permanently. Probably the length of time that the toxin has had a chance to act determines the permanent damage to the vessel wall. More potent than all other diseases to cause early arteriosclerosis is syphilis, and hence very careful inquiry should be made in regard to the possibility of infection with this

virus. Not only the fact of actual infection but the duration and thoroughness of treatment are important matters for the physician to know.

What is the patient's occupation? Has he been an athlete, particularly an oarsman? Has he been under any severe, prolonged, mental strain? Is he a laborer? If so, in what form of manual labor is he engaged? Such questions as these should never be overlooked, as they form the foundation stones of an accurate diagnosis, and early, accurate diagnosis, we repeat, is essential to successful therapy.

We have called attention to the factor of sustained high pressure in the production of arteriosclerosis. Constant overstretching of the vessels leads to efforts of the body to increase the strength of the part or parts. The material which is used to strengthen the weakened walls has a higher elastic resistance than muscle and elastic tissue, but a lower limit of elasticity, and is none other than the familiar connective tissue. In athletes, laborers, brain workers who are under constant mental strain, and in those whose calling brings them into contact with such poisons as lead, there is every factor necessary for the production of high tension and consequently of arteriosclerosis.

Another question in regard to personal habits is how much tobacco does the patient use and in what form does he use it? Our experience is that the cigar smoker is more prone to present the symptoms of arteriosclerosis than the cigarette smoker, the pipe smoker, or the one who chews the tobacco. A very irritable heart results not infrequently from cigarette smoking but such is almost always found in young men in whom the lesions of arteriosclerosis are exceedingly rare. The probabilities are that the arteriosclerosis in cigar smoking results from the slowly acting poison which causes a rapid heart rate with an increase of pressure.

Last but not least, and perhaps the most important question is, has the patient been a heavy eater? This we believe to be a potent cause of splanchnic arteriosclerosis with the resulting indigestion, cramp-like attacks, high blood pressure, etc. In a joking manner we are accustomed to remark, "Overeating is the curse of the American people." There is, however, much truth in that sentence. Osler, than whom there is no keener observer, states that he is more and more impressed with the fact that overloading the stomach with rich or heavy or spiced foods is to-day one of the first causes of arterial degeneration. It stands to reason that this is true. We know that organs exposed constantly to hard work undergo hypertrophy, and that the blood tension in those organs is high. Blood tension is, after all, dependent on capillary resistance, and if the capillaries are distended with blood, the resistance is great. The digestive organs can be no exception to this rule. Increased work means an increase of blood. This inevitably causes distension of the capillaries with stretching of the arteries and consequent damage to the walls. Once arteriosclerosis is present a vicious circle is established.

A man about forty-five consults us and says that he has noticed recently that he gets out of breath easily; in tying his shoes he experiences some dizziness. He finds that he has palpitation of the heart and possibly pain over the precordial region now and then. He notices also that he is irritable, that is his family tell him he is, and he notices that things that formerly did not annoy him, now are almost hateful to him. On examination, one finds a palpable radial, a somewhat hypertrophied heart and slightly accentuated second aortic sound. The blood pressure may be high. The urine may or may not reveal any abnormalities. Not infrequently, although no albumin may be found, there are hyaline casts. Such a case of arteriosclerosis is evi-

dently not to be regarded as early. Then the question arises how are we to recognize early arteriosclerosis? I do not believe that the solution of this problem lies entirely in the hands of the physician. Some men are fortunate enough to come up for an examination for life insurance before an observant doctor who recognizes the palpable artery, makes out the beginning heart hypertrophy and the slightly accentuated second aortic sound. The patient will tell you that he never felt better in his life. He gets up at seven, works all day, plays golf, drinks his three to six whiskies, and is proud of his physical development. But the great mass of people are not fortunate from this standpoint. They do not seek the advice of the physician until they are stretched out in bed. They boast of the fact that for twenty years they have never had a doctor. One may well say that it is a problem how to reach such persons. It seems to me that there can be but one way to do this. The people must be taught that the duty of a physician is just as much to keep them in health as it is to bring them back to health when they are ill. To that end people should be taught that at least twice a year they should be carefully examined. I do not mean that the patient should present himself to the doctor and, after a few questions the doctor say cheerfully, "You are all right." The patient should be systematically examined. That means a removal of the clothing and examination on the bare skin. Such coöperation on the part of patient and doctor would save the patient years of active life and make of the doctor, what his position entitles him to be, the benefactor to the community. Too often careless work on the physician's part lulls the patient into a false sense of security and he wakes up too late to find that he has wasted months or years of life. Early diagnosis of arteriosclerosis is only possible in exceptional cases unless people present themselves to the physi-

cian with the thought in mind that he is the guardian of health as well as the healer.

There are patients who go to the ophthalmologist for failing vision. Physically they feel quite well. They have been heavy eaters, hard workers, men and women who have been under great mental strain. On examination of the fundus of the eye there is found slight tortuosity of the vessels with possibly areas of degeneration in the retina. A careful physical examination will usually reveal the signs of arteriosclerosis elsewhere. We have mentioned frequently high tension as an early sign. This must be taken with somewhat of a reservation, for this reason: not infrequently a persistent high tension is the earliest sign of chronic nephritis. The arteries may be pipe stem in character and the heart small and flabby. However, if one watches for the palpably thickened superficial arteries (always bearing in mind the normal palpability as age advances) and the high tension, he cannot go far wrong in his treatment whether the case is one of chronic nephritis or of arteriosclerosis.

There is also this to bear in mind. Arteriosclerosis may be marked in some vessels and so slight in the peripheral vessels that it cannot with certainty be made out. But when the radials are sclerosed it is usually the case that similar changes exist in other parts. Then too, there may be marked changes at the root of the aorta leading to sclerosis of the coronary vessels alone, and the first intimation that the patient or any one else has that there is disease, may be an attack of angina pectoris. Except for symptoms on the part of the heart there is no way to make the diagnosis of sclerosis of the coronary arteries.

Differential Diagnosis.

In arriving at a diagnosis, when the question is whether or not arteriosclerosis is the main etiological factor, the most important fact to know is the age of the patient. Other points that have been dwelt on fully must of necessity also be borne in mind.

Possibly the chief conditions that may be confused with some of the results of arteriosclerosis are pseudo angina pectoris which may be mistaken for true angina pectoris, and ulcer of the stomach, appendicitis (?) or other inflammatory abdominal condition which may be mistaken for angina abdominalis.

Differential tables are sometimes of value in fixing the chief points of difference graphically.

Pseudo angina pectoris.	True angina pectoris.
Etiology rather certain; hysteria, neurasthenia, toxic agents, and reflex irritations.	Etiology not certain but almost always associated with arteriosclerosis of the coronary arteries and also aortic regurgitation.
No age is exempt. Usually in young people, chiefly females.	Age is important factor. Rare before forty, and males usually affected.
Paroxysms of pain occur spontaneously, are periodic and often nocturnal.	Paroxysms brought on by overexertions or excessive mental emotion. Rarely periodic.
Pain, while severe, is diffuse and sensation is of distension of heart. No sense of real anguish.	Intense pain, radiating down arm; heart felt as in a vise. Sense of anguish and impending dissolution.
Duration may be an hour or more.	Duration from few seconds to several minutes.
Restlessness and emotional symptoms of causative conditions are prominent.	Silent and fixed attitude, rigidity rather than restlessness.
Usually no increase in arterial tension.	Arterial tension is as a rule increased.
Prognosis favorable.	Prognosis most unfavorable.

In differentiating between ulcer of the stomach and angina abdominalis the following points may be of service:

Ulcer.	Angina abdominalis.
Occurs as a rule in young persons, more often females.	Only occurs in adults over forty who have been heavy eaters and drinkers, mostly males.
Pain of boring character increased by food and by certain positions with food in stomach. Felt through to left of spine.	Pain cramplike, diffuse, although more localized in epigastrium. Not necessarily any connection with food.
Occult blood found in stools.	No occult blood in stools.
Considerable anemia apt to be present.	Anemia more often absent.
Arterial tension usually low.	Arterial tension high. (Splanchnic sclerosis.)

Diseases in Which Arteriosclerosis Is Commonly Found.

There are certain more or less chronic diseases in which arteriosclerosis is found either as a separate disease or as a result of the chronic disease itself, or the sclerosis may be the cause of the disease. As examples of the first class are diabetes mellitus and cirrhosis of the liver. As examples of the second class are chronic nephritis, gout, syphilis, and lead poisoning. Examples of the third class have already been fully described. Then certain rare diseases that have been briefly described in this chapter, viz.: Raynaud's disease and erythromelalgia are frequently associated with demonstrable arteriosclerosis.

CHAPTER IX.

PROGNOSIS.

In a disease that presents as many vagaries as arteriosclerosis, it is not possible to give a certain prognosis. Unfortunately we do not as a rule see the arteriosclerotic until the disease is well advanced, or even after some of the more serious complications have taken place. By that time the condition is progressive, and while the prognosis is grave the individual may live a number of years.

It is fortunate for the arteriosclerotic that mild grades of the disease are compatible with a fairly active life. The disease in this stage may become arrested and the patient may live many years. Not only in the mild grades is this possible. Even patients with advanced sclerosis may enjoy good health provided the organs have not been so damaged as to render them unfit to perform their functions. The frequency with which we see advanced arteriosclerosis at the post mortem table as an accidental discovery, attests the truth of the foregoing statement. Yet how often does it happen that individuals, apparently in the best of health, suddenly succumb to an asthmatic or uremic attack, an apoplexy, cessation of the heart beat, or a rupture of the heart due to arteriosclerosis!

In order to arrive at an intelligent opinion in regard to prognosis certain factors must be taken into consideration, chief of which are: the seat of the sclerosis; the probable stage; the existing complications; and, last and most important, the patient himself. The whole man must be studied and even then our prognosis must be most guarded.

It is much more dangerous for the patient when the process is in the ascending portion of the arch of the aorta than when it has attacked the peripheral arteries. Here, at the root of the aorta, are the openings of the coronary arteries and the arteries supplying the brain are close by. The coronary arteries here control the situation. When loud murmurs are heard at the aortic orifice and the heart is evidently diseased, it is useful to divide the endocarditis into two types, the arteriosclerotic and the endocarditic. The etiology of the former is sclerosis and the prognosis is grave because of the liability, nay the probability, that the orifices of the coronary arteries will become narrowed. The etiology of the second type is in most cases rheumatic fever or some other infectious disease, and the prognosis is far better than in the first type. True, the two may be combined. In such a case, the prognosis is entirely dependent upon the course of the arteriosclerosis.

The involvement of the arteries in the kidneys is of considerable importance, for it is usually bilateral and widespread. As a rule, the disease makes but slow progress provided that the general condition of the patient is good, but at any time from a slight indiscretion or for no assignable cause, symptoms of renal insufficiency may appear and may rapidly prove fatal.

It must not be thought that because the localization of the arteriosclerosis in the peripheral arteries is usually the most favorable condition that it is therefore devoid of ill effects. On the contrary, very serious, even fatal, results may be brought about by interference with the circulation with resultant extensive gangrene of the part supplied by the diseased arteries. The amputation of a portion of a leg, for instance, may relieve, to some extent, an overburdened heart and prove life-saving to the patient, but the

neuritic pains are not necessarily relieved. The torture from these pains may be excruciating.

No stage of the disease is exempt from its particular danger. In the early stages of the disease before the artery or arteries have had time to become strengthened by proliferation of the connective tissue, there is the danger of aneurysm. Later, the very same protective mechanism leads to stiffening and narrowing of the arteries and hence to increased work on the part of the heart with all of its consequences. Thrombosis is favored, and where atheromatous ulcers are formed, embolism is to be feared.

As the complications and results of arteriosclerosis come to the front every one must be considered by itself and as if it were the true disease. There may be a slight apoplectic attack from which the patient fully recovers, but the prognosis is now of a grave character, as the chances are that another attack may supervene and carry off the subject. Yet, after an apoplectic attack, patients have lived for many years. Probably the most noted illustration of this is the life of Pasteur. He had at forty-six hemiplegia with gradual onset. He recovered with a resulting slight limp, did some of his best work after the stroke, and lived to be seventy-three years old. Yet the exception but proves the rule and the prognosis after one apoplectic stroke should always be guarded.

The first attack of cardiac asthma is to be looked upon as the beginning of the end. The end may be postponed for some time but it comes nearer with every subsequent attack. One may recover from what appears to be a fatal attack of cardiac asthma accompanied by edema of the lungs and irregular, intermittent, laboring heart, but the recovery is slow and the chances that the next attack will be the fatal one are increased.

The significance of albuminuria is difficult to determine.

The kidneys secrete albumin under so many conditions that the mere presence of albumin in the urine may have but little prognostic value. Many cases are seen where there is no demonstrable albumin, and yet the patient may suddenly have a cerebral hemorrhage. As a general rule the urine should be carefully examined, but not too much stress should be laid on the discovery of albumin and casts. It is not always possible to determine the extent of the kidney lesion by the urinary examination, yet at any time a uremic attack may appear and prove fatal.[1] One might say that the appearance of albumin in the urine of an arteriosclerotic where it had not been before, is a bad sign, and in making a prognosis this must be taken into consideration.

Bleeding from the nose is not infrequently seen in those who have arteriosclerosis. It can hardly be called a dangerous symptom as it can always be controlled by tampons. There are times when epistaxis is decidedly beneficial as it relieves headache, dizziness, and may avert the danger of a hemorrhage into the brain substance. It is rare to have nose bleed except in cases of high tension in plethoric individuals. My experience has been that it has saved me the trouble of bleeding the patient. It is always of serious import in that it indicates a high degree of tension, but there is scarcely ever any immediate danger from the nose bleed itself.

Intestinal hemorrhage is always a grave sign. As has been shown, arteriosclerosis of the splanchnic vessels not infrequently occurs, and an embolus or thrombus may completely occlude the superior mesenteric artery. The chances of the establishment of a collateral circulation are

[1] Recently Rowntree and Geraghty have shown that by means of the drug phenolsulphonephthalein it is possible to determine the functional ability of the kidneys, to differentiate cardiac edema from renal edema, and to predict uremic coma in cases not even suspected of having diseased kidneys. L. G. Rowntree and J. T. Geraghty, The Phthalein Test: An Experimental and Clinical Study of Phenolsulphonephthalein in Relation to Renal Function in Health and Disease. Arch. Int. Med., 1912, IX, 284.

small, as the arteries of the intestines are end arteries. Necrosis of the part follows, blood is found in the stools, and perforation or gangrene, or both, are apt to follow. There may be blocking of small branches only, leading to ulceration of the intestine. Under all conditions the prognosis is serious.

The general condition of the patient, his build, physical strength, powers of recuperation, etc., must be taken into account in giving a prognosis. The more powerful the individual, the more favorable, as a rule, is the prognosis, with this reservation always in mind, that the greater the body development, the greater is the heart hypertrophy, and the accidents from high tension must not be overlooked. Many puny individuals with stiff, calcified arteries go about with more ease than a robust man with thickened arteries only. The differentiation as pointed out by Allbutt (page 138), is well to keep in mind in giving a prognosis. It cannot be too strongly emphasized that it is the whole patient that we must consider and not any one system that at the time happens to be the seat of greatest trouble, and by its group of symptoms dominates the picture.

It is evident from what has been said that an accurate prognosis in arteriosclerosis is no easy matter. Were arteriosclerosis a simple disease of an acute character there might be grounds for giving a more or less definite prognosis. The most that can be said is that arteriosclerosis is always a serious disease from the time that symptoms begin to make themselves known. The gravity depends altogether on the seat of the greatest arterial changes, and is necessarily greater when the seat is in the brain than when it is in the legs or arms.

The attitude of the patient himself also determines to a great extent the prognosis. Some men, especially those who have always enjoyed good health, turn a deaf ear to

warnings and instead of ordering their lives according to the advice of the physician, persist in going their own way in the hope that the luck that has always been with them will continue to stand at their elbows. Neither firmness nor pleadings avail with some men. The only salve for the conscience of the physician is that he has done his best to steer the patient away from the shoals and breakers. In others who realize their condition and take advantage of the advice given as to the regulation of their lives, the prognosis is generally favorable.

To sum up the chapter in a few words, we should say: Always remember that the patient is a human being; study his habits and character and mode of life; look at him as a whole; take everything into consideration, and give always a guarded prognosis.

CHAPTER X.

PROPHYLAXIS.

Arteriosclerosis comes to almost every one who lives out his allotted time of life. As has been noted within, many diseases and many habits of life are conducive to the early appearance of arterial degeneration. Decay and degeneration of the tissues are necessary concomitants of advancing years and none of us can escape growing old. From the period of adolescence certain of the tissues are commencing a retrograde metamorphosis, and hand in hand with this goes the deposit of fibrous tissue which later may become calcified. The arterial tissue is no exception to this rule, and we have already shown that certain changes normally take place as the individual grows older, changes which are arteriosclerotic in type and are quite like those caused in younger people by many of the etiological factors of the disease.

We are absolutely dependent upon the integrity of our hearts and blood vessels for the maintenance of activity and span of life. Respiration may cease and be carried on artificially for many hours while the heart continues to beat. Even the heart has been massaged and the individual has been brought back to life after its pulsations have ceased, but such cases are few in number. We cannot live without the heart beat and the prophylaxis of arteriosclerosis consists in the adjustment of our lives to our environment, so that we may get the maximum amount of work accomplished with the minimum amount of wear and tear on the blood vessels.

The struggle for existence is keen. Competition in every profession or trade is exceedingly acute, so much so that to rise to the head in any branch of human activity requires exceptional powers of mind. Among those who are entered in this keen competition, the fittest only can survive for any period of time. The weaklings are bound to succumb. A scion of healthy stock will stand the wear and tear far better than will the progeny of diseased parentage.

It is only necessary to call attention to the part that alcohol, syphilis and insanity play in heredity. These have been discussed fully in the earlier part of this book.

We live rapidly, burning the candle at both ends. It is not strange that so many comparatively young men and women grow old prematurely. While heredity is a factor as far as the prophylaxis of arteriosclerosis is concerned, of far more importance is the mode of life of the individual. Scarcely any of us lead strictly temperate lives. If we do not abuse our bodies by excessive eating and drinking and so wear out our splanchnic vessels and cause general sclerosis by the high tension thereby induced, we abuse our bodies by excessive brain work and worry with all their multitudinous evils. The prophylaxis of arteriosclerosis might well be labeled, "The plea for a more rational mode of life." Moderation in all things is the keynote to health, and to grow old gracefully is an art that admits of cultivation. Excesses of any kind, be they mental, moral, or physical, tend to wear out the organism.

People habitually eat too much; many drink too much. They throw into the vascular system excessive fluid combined frequently with toxic products that cause eventually a condition of high arterial tension. It has been shown how poisonous substances absorbed from the intestines have some influence on the blood pressure. Anything that causes constant increase of pressure should be studiously avoided.

Mild exercise is an essential feature of prophylaxis. One may, by judicious exercise and diet, make of himself a powerful muscular man without, at the same time, raising his average blood pressure. The man who goes to excess and continually overburdens his heart, will suffer the consequences, for the bill with compound interest will be charged against him. It is a great mistake for any one to work incessantly with no physical relaxation of any kind, and yet, after all, it is not so much physical relaxation that is necessary, as the pursuit of something entirely different, so that the mind may be carried into channels other than the accustomed routes. Diversification of interests is as a rule restful. That is what every man who reaches adult life should aim at. Hobbies are sometimes the salvation of men. They may be ridden hard, but even then they are helpful in bearing one completely away from daily cares and worries. The man who can keep the balance between his mental and physical work is the man who will, other things being equal, live the longest and enjoy the best health.

Nowadays the trend of medicine is toward prophylaxis. We give the State authority to control epidemics so far as it is possible by modern measures to control them.

We urge over and over again the value of early diagnosis in all chronic diseases, for we know that many of them, and this applies particularly to arteriosclerosis, could be prevented from advancing by the recognition of the condition and the institution of proper hygienic and medicinal treatment.

It is the patent duty of every physician to instruct the members of his clientele in the fundamental rules of health. Recently the President of the American Medical Association, in his address before the 1908 meeting, urged the dissemination of accurate knowledge concerning diseases among the laity. While this may be done by City and State

Boards of Health, it seems far better for the modern trained physician to work among his own people. With concise information concerning the modes of infection and the dangers of waiting until a disease has a firm hold before consulting the health mender, people should be able to protect themselves from infections and be able to nip chronic processes in the bud. But it is difficult to turn the average individual away from the habit of having a drug-clerk prescribe a dose of medicine for the ailment that troubles him. It is really unfortunate that most of the pains and aches and morbid sensations that one has speedily pass away with little or no treatment. Herein lies the strength of charlatanism and quackery. Unfortunate, yes, for a man cannot tell whether the trivial complaint from which he suffers is any different from the one that was so easily conquered six months ago. But instead of recovering, he grows worse. Hope that springs eternal in the human breast, leads him to dilly-dally until he at last seeks medical advice, only to find that the disease has made such progress that little can be done.

Instruct the public to consult the doctors twice a year. The dentists have their patients return to them at stated intervals only to see if all is well. How much more rational it would be if men and women past the age of forty had a physical examination made twice a year to find out if all is well.

The prophylaxis of arteriosclerosis is moderation in all the duties and pleasures of life. This in no sense means that a man has to nurse himself into neurasthenia for fear that something will happen to him. As one grows in years exercise should not be as violent as it was when younger, and food should be taken in smaller quantities. Many forms of exercise suggest themselves, particularly walking and golf. Walking is a much neglected form of exercise which,

in these modern days with our thousand and one means of locomotion, is becoming almost extinct. There is no better form of exercise than graded walking. To strengthen the heart selected hill climbing is one of the best therapeutic methods that we have. The patient is made to exercise his heart just as he is made to exercise his legs, and as with exercise of voluntary muscles comes increase in strength, so by fitting exercise may the heart muscle be increased in power. A warning should be sounded however against over exercise. This leads naturally to hypertrophy with all its disastrous possibilities. Men who have been athletes when young should guard against overeating and lack of exercise as they grow older. Many of the factors which favor the development of arteriosclerosis are already there, and a sedentary, ordinary life, such as office all day, club in afternoon, a few drinks and much rich food, will inevitably lead to well-advanced arterial disease.

Karl Marx in his famous Socialistic platform said: "No rights without duties; no duties without rights." So we may paraphrase this and say: "No brain work without moderate physical exercise in the open air; no physical exercise without moderate brain work."

There is yet one other point that is important, the combination of concentrated brain work and constant whiskey drinking. This is most often seen in men of forty-five to fifty-five, heads of large business concerns who habitually take from six to twelve drinks of whiskey daily, and with possibly a bottle of wine for dinner. Such men appear ruddy and in prime health but, almost invariably, careful examination will reveal unmistakable signs of arterial disease. There is usually the enlarged heart and pulse of high tension with or without the trace of albumin in the urine. The lurking danger of this group of manifestations has so impressed the medical directors of several of the large insur-

ance companies that a blood pressure reading must be made on all applicants over forty years of age. Should high blood pressure be found, the premium is increased, as the expectation of life is proportionately shorter in such men than in normal persons.

Therefore, let every physician act his part as guardian of health. Only in this way is the prophylaxis of arteriosclerosis possible.

CHAPTER XI.

TREATMENT.

Although it has been rather dogmatically stated (vide supra) that every one who reaches old age has arteriosclerosis, it must not be inferred that absolutely no exceptions to this rule are found. Cases are known where persons of ninety years even had soft arteries, and we have seen persons of sixty whose arteries could not be palpated. When infants and children are seen with considerable sclerosis, it proves that, after all, it is the quality of the tissue even more than the wear and tear, that is the determining factor in the production of arteriosclerosis. It would be well if those who cannot bring healthy progeny into the world were to leave this duty to those who can.

In general the treatment of arteriosclerosis is prophylactic and symptomatic. In the preceding chapter we had something to say about prophylaxis in general; we must again refer to it in detail.

Arteriosclerosis is essentially a chronic progressive disease, and the secret of success in the management of it is not to treat the disease or the stage of the disease, but to treat the patient who has the disease. To infer the stage of the disease from the feeling of the sclerosed artery, may lead to serious mistakes. Persons with calcified arteries may be perfectly comfortable, while those with only moderate thickening may have many severe symptoms. The keynote is individualization. It is manifestly absurd to treat the laboring man with his arteriosclerosis as one would treat the successful financier. The habits, mode of

life, every detail, should be studied in every patient if we expect to gain the greatest measure of success in the treatment. One may treat fifty patients who have typhoid fever by a routine method and all may recover. Individualizing, while of great value in the treatment of acute diseases, yet is not absolutely essential in order that good results may be obtained. Far different is it when treating a disease like arteriosclerosis. One who relies on textbook knowledge will find himself at a loss to know what to do. Textbooks can only outline, in the briefest manner, the average case, and no one ever sees the average book case. At the bedside with the patients is the place to learn therapeutics as well as diagnosis. All that can be hoped for in outlining the treatment of arteriosclerosis is to lay down a few principles. The tact, the intuition, the subtle something that makes the successful therapeutist, cannot be learned from books. So the man who treats cases by rule of thumb is a failure from the beginning. There are certain general principles that will be our sheet anchors at all times and for all cases. The art of varying the application of these fundamentals to suit the individual case, is not to be culled from printed words.

Hygienic Treatment.

Every man is more or less the arbiter of his own fate. Granted that he has good tissue to begin life, his own habits and actions determine his span of comfortable existence. No one cares to live after his brain begins to fail, and the failing brain is often due to disease of the cranial arteries. The hygienic treatment resolves itself into advice in regard to prophylaxis.

First and foremost is exercise. It has seemed to us that the revival of out-of-door sports is one of the best signs of

promise of the preservation of a virile, hardy race. That women, as well as men, indulge in the lighter forms of out-of-door exercise should bring it about that the coming generation will start in life under the most advantageous conditions of bodily resistance.

Among all the forms of exercise, golf probably is the best. It is not too violent for the middle-aged man, yet it gives the young athlete quite enough exercise to tire him. It is played in the open. One is compelled to walk up and down in pleasant company, for golf is essentially a companionable game, while he reaps the full benefit of the invigorating exercise. The blood courses through the muscles and lungs more rapidly; the contraction of the skeletal muscles serves to compress the veins and so to aid the return of blood to the heart: the lungs are rendered hyperemic, deeper and fuller breaths must be taken; oxidation is necessarily more rapid, and effete products, which if not completely oxidized would possibly act as vasoconstrictors, are oxidized to harmless products and eliminated without irritating the excretory organs.

Other forms of out-door exercise that can be recommended are tennis, canoeing, rowing, fishing, horseback riding, swimming, etc. Tennis is the most violent of all the sports mentioned and might readily be overdone. Rowing as practiced by the eights at college is undoubtedly too violent a form of exercise, and may be productive in later life of very grave results. Canoeing is a delightful and invigorating exercise. The muscles of the arms, shoulders, and trunk are especially used, the leg muscles scarcely at all. Nevertheless, the deep breathing that necessarily comes with all chest exercises aerates every portion of the lungs, and is of great benefit to the whole body.

Swimming as an exercise has much to recommend it. In

this sport all the muscles take part and at the same time the chest is broadened and deepened.

All these methods of using the muscles to keep oneself in trim, so to speak, are part and parcel of the general hygienic mode of life that is conducive to a healthy old age. Exercise can be overdone, as eating can be overdone. Both are essential and yet both can be the means of hastening an individual to a premature grave.

When the arteriosclerosis has advanced so far that it is easily recognizable, certain forms of exercise should be absolutely prohibited. Such are tennis, rowing and swimming. Horseback riding to be allowed must be strictly supervised. At times this may be an exceedingly violent exercise. As an out-of-door sport, there is nothing that equals golf. The physician, knowing the character of the course, and the length of it, can say to his patient that he may play six, nine, twelve, or eighteen holes, depending on the patient's condition.

For those who are not able to get out, exercise in the room with the windows open must take the place of out-of-door sports. Here the use of chest weights is a most excellent means of keeping up the tone of the muscles. By adjusting the weights, the exercise may be made light, medium, or heavy. Every physician should be familiar with the chestweight exercises. They are not as good as open air exercise but they undoubtedly have been the means of saving years of life to many patients with arterial disease.

There comes a time when all forms of exercise must be prohibited on account of the dyspnea, edema, dizziness, etc. It seems unwise to keep such a patient in bed, even though the edema be considerable. Once on his back in bed he becomes weak, and the danger of edema of the lungs or

hypostatic congestion of the bases, with subsequent broncho-pneumonia, is very great. Although such persons can not exercise actively, they should have passive exercise in the form of massage, carefully given, so that no injury is done to the rigid vessels. It is possible to rupture a vessel, the walls of which are encrusted with lime salts, and full of small aneurysmal dilatations. Every patient must be watched carefully and measures instituted for the individual.

Balneotheraphy.

As a tonic and invigorator, the cold or cool bath (shower or tub), in the morning on arising can be highly recommended. It promotes skin activity, is a stimulant to the bowels and kidneys and to the general circulation, besides being cleansing. We find to-day that the morning bath has become such a necessity to the average American that all new hotels are fitted with private baths, and old hotels, in order to get patronage, are arranging as many baths connected with sleeping rooms as is possible. Our generation assuredly is a ruddy, clean-bodied one. What the actual results of this out-door life and frequent bathing will be for the race remains to be seen, but one cannot but feel that it must build up a stronger, more resistant race of people, who not only enjoy better health than did their forefathers, but enjoy it longer.

Not every one can stand a cold bath. It is folly to urge it on one to whom it is distasteful, or on one who does not feel the comfortable glow that should naturally result. For the well, or those with a tendency to arteriosclerosis, or those in whose families there have been several members who had early arteriosclerosis, such proceedings as recommended could not be improved upon. However, for the person who has well recognized sclerosis, only warm baths

should be advised, and these not daily. The water should be at a temperature of 90–95 degrees F. Care should be taken that persons sent to spas be cautioned against hot baths. It is not inconceivable that the increased force of the heart beat that accompanies a hot bath might be sufficient to rupture a small cranial vessel. Hence, Turkish and Russian baths should be most unqualifiedly condemned. As a matter of fact, persons vary so in their habits with regard to bathing that what might suit one person would do another much harm.

Personal Habits.

The personal habits of the individual, more than any other factor, determine whether or not arteriosclerosis sets in early in his life. The man or woman who is moderate in eating and drinking, sees that the kidneys are kept in good condition, and attends strictly to regularity of the bowels, lays a good basis for the measure of health which is so essential for happiness. It has been shown that sclerosis of the splanchnic vessels may be due to constant irritation of toxic products elaborated in digesting constantly enormous meals. In obstinate constipation, many poisons, the nature of which we do not know, are absorbed and circulate in the blood. We have not sufficient data to prove that constipation favors the production of arteriosclerosis, but our impression has been that it does favor it. Constipation can often be relieved by a glass of water before breakfast, a regular time to go to stool, and abdominal massage or exercises. Some maintain that it is a bad habit only, and can be readily overcome. Whatever is done, avoid leading the patient into the drug habit, for the last state of the patient will be worse than the first. Habits of sleep are not of such great importance. Most persons get enough sleep except when under severe mental strain. Most adults

need from seven to eight hours' sleep, although some can do all their work and keep in prime health on five or six hours' sleep.

Tobacco has been accused of causing many ills and has been thereby much maligned. We cannot see that the use of tobacco in any form in moderation is harmful to most men. Undoubtedly the blood pressure is raised when mild tobacco poisoning occurs, and individual peculiarities of reaction to the weed are multitudinous. But to condemn offhand its use is the height of folly. There is no reason why the arteriosclerotic who has always used tobacco in moderation, should not continue to use it, whether he smoke cigarettes, cigars, or pipe. His supply should be decreased, but there is no sense in depriving a man of one of the solaces of life, unless, as is sometimes the case, abstinence is easier for the patient than moderation.

As for alcohol, opinions differ widely. Some see in alcohol one of the most frequent causes of arteriosclerosis; others do not believe that the part played by alcohol is a serious one, only in conjunction with other poisonous substances is it dangerous. Probably unreasoning fanaticism has had much to do with the wholesale condemnation of alcoholic beverages. The general effect of alcohol is to lower the blood pressure by causing marked dilatation of all the vessels of the skin. True, the alcohol circulates in the blood, and is broken up in the liver, and this organ would seem to bear the brunt of the harm done. Alcoholic drinks in moderation, I do not believe have any deleterious effect on health. On the contrary, I believe that they may in some cases assist digestion and assimilation. Indiscriminate indulgence is to be condemned, as is overindulgence in exercise or eating. What may be moderate for A, might be excessive for B. Every man is then the arbiter of his own fortune and within his own limits can indulge moder-

ately (a relative term after all) without fear of doing himself harm. In advanced arteriosclerosis it is necessary to decrease the supply of alcohol just as it is necessary to cut down the food supply. This must rest entirely on the judgment of the physician, who must not act arbitrarily, but must have his reasons for every one of his orders.

Dietetic Treatment.

Most persons eat too much. We not only satisfy our hunger, but we satisfy our palates, and, instead of putting substantial food stuffs into our stomachs, we frequently take unto ourselves concoctions that defy description.

Food stuffs are composed of one or all of three classes: (1) proteids, (2) fats, (3) carbohydrates. As examples of the first are beef and white of egg; of the second, the oils, butter, lard; of the third, sugar, potato, beet, corn, etc.

The physiologists and chemists have shown us that both endogenous and exogenous uric acid in excess will cause a rise of blood pressure, but the bodies most concerned in the production of elevated blood pressure are the purin bodies, those organic compounds which are formed from proteids, and represent chemically a step in the oxidation of part of the proteid molecule to uric acid. Red meat contains more of the substances producing purin bodies than any other one common food stuff, and for this reason the excessive meat eater is, *ceteris paribus*, more apt to develop arteriosclerosis comparatively early in life.

The fats and carbohydrates contain practically no substances that react on the body of the ordinary individual in a deleterious manner during their digestion. The extra work that is put on the heart by the formation of many new blood vessels in adipose tissue is the only harmful effect of over indulgence in these food stuffs.

It has been found that nitrogen equilibrium can be maintained at a wide range of levels. Formerly 135–150 gms. of proteid daily were considered necessary for a man doing light work. Now it is known that half that amount is sufficient to keep one in nitrogenous equilibrium, and to enable one to keep his weight. A person at rest requires even less than that. One who is engaged in hard physical labor burns up more fuel in the muscles, and so must have a larger fuel supply.

Although we habitually eat too much we drink too little water. For those who have any form of arterial disease an excess of fluid is harmful, as the vessels become filled up and a condition of plethora results, which necessarily reacts injuriously on the heart and circulation. The drinking of a glass of water during meals is, in the author's opinion, good practice. The water must be taken mouthful at a time, and not gulped down. If this is done, there results sufficient dilution of the solid food to enable the gastric juices successfully and rapidly to reach all parts of the meal.

Some are in favor of a rigid milk diet for those who have arteriosclerosis. Some men have lived on nothing but milk for several years and have not only kept in good health, but have actually gained weight and led at the same time active lives. It has been held by others that rigid milk diet is positively harmful on account of the relatively large quantity of calcium salts that are ingested. This was thought to favor the deposition of calcareous material in the walls of the already diseased arteries. While possibly there may be some danger of increased calcification, the majority of clinicians are in favor of a milk cure given at intervals. Thus the patient is made to take three to four quarts daily for a period of a month. There is then a

gradual return to a general diet, exclusive of meat, for several weeks, then another rigid milk diet period.

If we are bold enough to follow Metchnikoff in his theories of longevity, we might advise resection of the large intestine, on the ground that it is an enormous culture tube that produces prodigious amounts of poisonous substances which are thrown into the general circulation. To combat such a grave (?) condition as the carrying of several feet of large intestine, we are recommended to take buttermilk or milk soured by means of the *b. acidus lacticus.* Clinical experience has taught that in arteriosclerosis buttermilk is of great value, whether it be the natural product, or made directly from sweet milk by the addition of the bacilli. The latter is a smoother product and has, to my mind, a delightful flavor. It may be diluted with Vichy or plain soda water. Cases that cannot take milk or any other food will often take buttermilk, and do well on this restricted diet. From two to four quarts daily should be taken. It should be drunk slowly as should milk.

Medicinal.

It has long been thought that the iodides have some specific effect on the advancing arteriosclerosis, checking its spread, if not really aiding nature to a limited restoration of the diseased arteries. It is possible that the eulogies upon the iodides owe their origin to the successful treatment of syphilitic arteriosclerosis, in which condition these drugs have a specific action. However that may be, there is no doubt that the administration of sodium or potassium iodide is good therapeutics in cases of arteriosclerosis.

Unfortunately many persons have such irritable stom-

achs that they cannot take the iodides, even though they be diluted many times. They may be made less irritating by giving them with essence of pepsin. Unless the case is syphilitic, it is doubtful if it is of value to increase the dose gradually until a dram or even more is taken three times daily after meals. Usually a maximum dose of ten grains seems to be quite sufficient. This may be taken three times a day, well diluted, for three months. There follows a month's rest, then the treatment is resumed for another period of three months, and so on. Either sodium or potassium iodide in saturated solution may be given. The sodium salt is possibly less irritating, and contains more free iodine than the potassium salt, although the latter is more generally used. The strontium iodide may also be used.

One sees a patient now and then who cannot take the iodides, however they may be combined. For such patients one may obtain good results with iodopin, sajodin, or other of the preparations put up by reputable firms. Personally, I have never yet seen a patient who could not take the ordinary iodides in some form or other, and I am opposed to ready made drugging.

The action of the iodides is to lower the blood pressure, and they are of greatest value when the blood pressure is high, and when headache and precordial pain are present.

When the case is moderately advanced, very mild doses, gr. ⅓, morning and evening, of the thyroid extract may be given. It is generally believed that the internal secretion of the thyroid and the adrenal are antagonistic. That the thyroid secretion lowers blood pressure is certain, possibly on account of its iodine content. Some combinations of iodine and thyroid such as the iodothyroidin have been used and have had some measure of success attributed to them.

Hypertension does not always demand active measures

for its reduction. Viewed from the physiological standpoint, hypertension is but the expression of a compensating mechanism which is designed to keep the blood moving through narrowed channels. Heart hypertrophy then is absolutely essential to the maintenance of life. It has been said that the highest blood pressures occur in chronic disease of the kidneys. The poisonous substances produced in the kidneys must exert their action through absorption into the general blood stream. This toxin may be completely eliminated, if we accept as our criterion the reduction of tension to normal together with the complete return of the affected individual to health. A concrete example is as follows: A man aged 44 years was brought to the Milwaukee County Hospital in coma. His blood pressure was over 280 mm. Hg., his urine contained considerable albumin and many casts. He had general anasarca. Venesection was done at once and 300 cc. blood obtained. Immediately following this operation the pressure was 210 mm., but within twelve hours it was again above 280 mm. He was given no medication to reduce pressure except that he was freely purged. He was given a steam sweat bath daily. Frequent blood pressure readings were taken. Within seven days the pressure was 130 mm. He had, in the meantime, completely recovered from his symptoms. He was kept in the hospital for two weeks longer assisting in the work on the ward, and he was discharged with a pressure (systolic) between 130 and 136 mm. The treatment was rest in bed, free purging, venesection, and sweat baths, simple but exceedingly effective.

Should there be actual indications for reducing the blood pressure, I must admit that it cannot always be done. The majority of cases will do well on the sodium nitrite or erythrol tetranitrate. However, these do not always lower blood pressure and keep it within normal limits. When a

man has very high tension we do not wish to reduce it to what it should normally be for the age of the patient, as symptoms of collapse might set in at any time under such conditions.

Observations made with the sphygmomanometer [1] show that the effect of nitroglycerin is transient or of no effect except in doses which are relatively enormous (one drop of the one per cent solution given every hour). Sodium nitrite may lower the blood pressure but the effects will have worn off in two hours. It is the same with erythrol tetranitrate. Sodium sulphocyanate in doses of from one to three grains three times a day is highly recommended by some. My own experience with it does not lead me to believe that it is of any great value in hypertension. It, however, may be tried. As a matter of fact the drug treatment of hypertension, when it becomes necessary to treat this condition with drugs, has suffered a notable set-back since more careful control has been made with the blood pressure instruments. In giving any of the depressor drugs their action should be controlled by blood pressure measurements, for only in this way can we be sure that the drug is exerting its physiological effect and we may expect results. The individual reaction to these drugs varies greatly and no rule for dosage can be dogmatically laid down. The only successful therapy is rigid individualization. This is the keystone to treatment in cases of arteriosclerosis and high tension.

It must not be inferred from what has been said that the nitrites are of no value. They are of decided value but they have their limitations. The most evanescent of these drugs is amyl nitrite. This is put up in the form of capsules, or pearls, containing from one to three minims. When

[1] See Jos. L. Miller, Hypertension and the Value of the Various Methods for its Reduction. Jour. Amer. Med. Assoc., 1910, LIV, p. 1666.

it is desired to dilate the peripheral vessels suddenly, one or two of these capsules are broken in a cloth held to the nose. The effect is almost instantaneous. There is flushing of the face and other peripheral vessels, particularly near the head, denoting a relaxation and widening of the bed of the blood stream, and a consequent decrease in pressure in the arteries. These effects are over in a short while. It is only used in attacks of cardiac spasm, as in angina pectoris. Nitroglycerin, the Spiritus Glonoini of the U. S. P., acts in about the same manner as amyl nitrite but the effects last usually a trifle longer. One drop of the one per cent solution may be given every hour until physiological effects are produced. It may be given hypodermically. This may be a means of reducing pronounced high tension. This drug has been found of benefit especially in cases where arteriosclerosis combined with chronic nephritis causes cardiac asthma. The other drug which may be of service in these conditions, one whose sphere of action is somewhat broader, because its effects are more lasting, is sodium nitrite. This is given in water in doses of one to three or five grains every four hours. Some have objected to the use of this drug, but my experience has made me place considerable confidence in its harmlessness, provided that the patient is carefully watched. This, however, applies to all of the nitrite compounds. My experience with erythrol tetranitrate is not large. It may be used in place of sodium nitrite.

For a mild case, one often finds that sweet spirits of niter is sufficient to control the pressure and relieve the distressing symptoms, and it is undoubtedly the least harmful of all the nitrites. Drugs that are of great value, but of which little is noted in textbooks, are aconite and veratrum viride. Both of these drugs are well known to be marked circulatory depressors. Veratrum viride in my ex-

perience should be very cautiously used, and never used unless a trained attendant is constantly at hand. With regard to aconite I have no such feeling, and a mixture of tincture of aconite and spiritus etheris nitrosi may be given for several weeks with no fear of doing any harm. Personally, of all the drugs mentioned, I prefer the nitrite of sodium or the combination just given. They may be advantageously alternated.

My own feeling is that the most successful means of treatment of acute high tension is without the use of drugs. The most important measure is absolute rest in bed. This often suffices to lower the blood pressure and to arrest the symptoms produced by high tension. Venesection I believe is also of value. True the arterioles appear to contract almost immediately upon the lessened quantity of blood, or there is immediate interchange of serum from the tissues which brings the blood volume back to the original amount. Whatever happens the pressure is not greatly reduced, at times not reduced at all, but often the symptoms are relieved. Hot packs or sweat baths assuredly do reduce the pressure in many cases. This seems to me to be an exceedingly valuable measure. Finally the diet should be nourishing, but very light, not too much fluid should be ingested, and the bowels should be freely opened.

With the fibrolysin of Merck, I have had no experience. Some men assert that they have had good results from its use, but on the whole the evidence is not highly favorable.

Morphine is invaluable. No drug is of such value in the nocturnal dyspneic attacks that occur in the late stages of arteriosclerosis when the heart or the kidneys are failing. Morphine not only relaxes spasm and quiets the cerebral centers, but is an actual heart stimulant under such conditions, and should never be withheld, as the danger of the

patient's becoming addicted to its use is more fanciful than real.

As heart stimulants, one may use strychnine, spartein, caffein, or camphor. In desperate cases, where a rapidly diffusible stimulant is needed, a hypodermic syringefull of ether may be given, and repeated in a short while.

Several years ago a so-called serum was brought out by Trunecek which was said to have a favorable effect on the metabolism of the vessel walls. It was given at first hypodermatically or intravenously but the former method was painful. It was later stated that given by mouth it acted just as well. The results with the Trunecek serum have not come up to the expectations that the early favorable reports promised. The original serum was composed as follows: NaCl, 4.92 gm.; $Na_2 SO_4$, 0.44 gm.; $Na_2 CO_3$, 0.21 gm.; $K_2 SO_4$, 0.40 gm.; aqua destil. q. s. ad. 100.0 cc. Later this was modified for internal use to the following prescription:

R	Natrii chlor.	10.	gm.
	Natrii sulphat.	1.	gm.
	Natrii carbonat.	0.40	gm.
	Natrii phosphat..	0.30	gm.
	Calcii phosphat.		
	Magnesii phosphat. aa	0.75	gm.

M. Ft. cachets No. XIII.

The contents of every cachet corresponds to 15 cc. of the fluid serum or to 150 cc. of blood serum. The preparation called antisclerosin consists of the salts contained in the serum. As to its efficacy, I cannot judge, as I have never felt that it was worth while to use it. Reports of cases in which it has been tried do not speak very highly of it.

In the general treatment of arteriosclerosis, there is no one factor of more importance than the regular daily bowel movement. Attention to this may save the patient much discomfort and even acute attacks of cardiac embarrass-

ment. The choice of the purgative is immaterial, with this reservation only, that the mild ones, such as cascara, rhubarb, licorice powder and the mineral waters, should be thoroughly tried before we resort to the more drastic purgatives. Phenolphthalein in 3 to 5 grain doses acts remarkably well in some people as a pleasant laxative. Agar-agar with or without cascara may be useful.

The old Lady Webster dinner pill is an excellent tonic aperient. When the heart is embarrassed and edema of the legs and effusion into the serous cavities have taken place, then it becomes necessary to use the drastic purgatives that cause a number of watery movements. Epsom salts given in concentrated form, elaterin gr. 1–12, the compound cathartic pill, blue mass and scammony, or even croton oil may be used. Since the observation of a greatly congested intestine from a patient who had been given croton oil, I have ceased to use this purgative, and I doubt much if its use is ever justifiable in these cases.

The management of the ordinary case of arteriosclerosis resolves itself into a careful hygienic and dietetic regime with the addition of the iodides, aconite, or the nitrites. A diet consisting of very little meat, alcohol in moderation or even absolutely prohibited, and not too much fluid should be prescribed. Condiments and spices should also be used sparingly. Cold baths, shower baths, cold and hot sheets alternating, are of great benefit in assisting the heart to do its best work by making the large capillary area of the skin more permeable. It is not true that such baths raise the blood pressure so markedly. Certain acts, as sneezing, violent coughing, etc., increase the blood pressure much more than judicious bathing.

Symptomatic Treatment.

The fact that arteriosclerosis really loses much of its own identity and, in later stages, becomes merged with the symptomatology of the diseases of various organs, as the kidney, brain, heart, compels us, for completeness' sake, to say a few words about the treatment of these complications.

One of the results of arteriosclerosis of the coronary arteries, angina pectoris, demands prompt treatment. In the acute attack, the chief object is to relieve the spasm and pain. Pearls of amyl nitrite should be inhaled, and morphine sulphate with atropine sulphate given hypodermatically at the very earliest moment. It is senseless to withhold morphine. The only possible reason for withholding it would be uncertainty as to the diagnosis. It is probably better to err on the safe side, and should the case prove to be one of pseudo angina, in the next attack sterile water can be given instead of the morphine and atropine.

When a patient is seen in the condition of broken compensation with the much dilated heart, anasarca, dyspnea and suppression of urine, there is no better practice than venesection. Especially is this valuable when the tension is still fairly high and the individual is robust. Following the abstraction of six to eight ounces of blood the whole picture changes, so that a man who a short while before was apparently at death's door, notices his surroundings and takes an interest again in life. This should be followed up with thorough purgation, and cardiac stimulants should be ordered. In such cases digitalis is useful, but its action is never so striking as in cases of this general character due to uncompensated valvular disease. It must be remembered that in arteriosclerosis the changes in the myocardium must be of a considerable grade for the heart to give away. Therefore, digitalis cannot be expected to act on

a diseased muscle as it acts on a comparatively healthy muscle. It is only in such cases of broken compensation that digitalis should ever be used. It is a vasoconstrictor as well as a cardiac stimulant, and hence in choosing a drug to increase the working power of the heart when there is only arteriosclerosis and a weak heart, one should put digitalis out of the list. It is absolutely contraindicated in Stokes-Adams syndrome.

There are, however, some cases, especially those with transudations, when digitalis may be carefully tried even though high tension be present. It is sometimes of advantage to combine digitalis with the nitrites although they are said to be physiologically incompatible.

Still another drug, that is of great value in conditions such as have been described, is diuretin. This may be given in capsule or tablets, grs. x. three times daily. There is only one caution to express in the use of this drug. It does not act well when the kidneys are the seat of chronic inflammatory changes; in fact, actual harm may be done by administering the drug under such conditions.

For the pain in aneurysm, nothing (except, of course, morphine) is so valuable as iodide of potassium. Patients who are suffering agony, when put to bed and given KI grs. x. three times a day, soon lose all the distressing symptoms. This applies particularly to aneurysms of the arch of the aorta.

When the sclerosis has affected the cerebral arteries to such an extent that symptoms result, the case is, as a rule, exceedingly grave. Not much can be done except to relieve the headaches and keep down the blood pressure, if this is high, by means of rest in bed, the iodides, aconite, or the nitrites. The cases of transient monoplegias or hemiplegias can be much relieved by careful hygienic measures and judicious administration of drugs. Much ingenuity is some-

times required to overcome the idosyncrasies of patients, but care and patience will succeed in surmounting all such difficulties.

The treatment of intermittent claudication is the treatment of arteriosclerosis in general. Sometimes the circulation in the affected leg or legs is much helped by daily warm foot baths. Light massage might be tried and the galvanic current may be used once or twice daily.

There are a few distressing symptoms that occur usually late in the disease, when complications have already occurred, which frequently baffle the therapeutic skill of the physician. The chief of these—insomnia, dyspnea, and headache—may not be late manifestations, but insomnia and headache are frequently associated with the moderately advanced stages of arteriosclerosis. At times all the symptoms seem to be due to the high tension, the relief of which causes them to disappear. There are, unfortunately, times when high tension is not responsible for the headache and insomnia. Under these circumstances such drugs as trional, veronal, amylene hydrate, ammonol, etc., may be tried until one is found which produces sleep. For the headaches, phenacetin, alone or in combination with caffein and bromide of sodium, may be tried. Acetanilid, cautiously used, is at times of value. There have been cases of arteriosclerosis with low blood pressure, accompanied by severe headaches, that have been relieved by ergot. Codeine should be used with care, and morphine only as a very last resource.

Great care must always be exercised in giving drugs that depress the circulation, for it is easily conceivable that more harm than good can come from injudicious drugging.

CHAPTER XII.

ARTERIOSCLEROSIS IN ITS RELATION TO LIFE INSURANCE.

The value of the early recognition of cases of arteriosclerosis and hypertension has been spoken of within, but it needs to be further emphasized. There is perhaps no class among physicians to whom is afforded a better opportunity of seeing early cases than the medical examiners of life insurance companies.

The relationship between a patient and the physician whom he consults, and the applicant for life insurance and the examiner are diametrically opposite. In the former the patient desires to conceal nothing and the physician is called upon to diagnose and treat disease. In the latter the applicant, a presumably healthy person, may have much to conceal and the examiner is there to pass upon the state of health. The question is this—"Is the applicant now in good health?" It becomes then of vital importance for the examiner to be able to detect among other abnormal conditions the incipient signs of arteriosclerosis and of hypertension. Parenthetically it may be stated that arteriosclerosis and hypertension are not one and the same disease as has been so frequently insisted upon within, the former may occur without the latter but the latter cannot from its very nature be present for long without arterial thickening supervening. It is necessary in discussing the question here to group the two conditions together in order to prevent needless repetition.

Such a case as the following is common. A successful business man of forty-four years was brought to me by an agent in 1905 for examination. The man was six feet tall, weighed 218 lbs., had a ruddy color and looked to be the picture of health. He was not strictly intemperate, he never became intoxicated, but every day he drank three or four whiskies and often he had a bottle of wine for dinner in the evening. When he was examined his pulse was of good quality and owing to the fleshiness of the wrist it was difficult to say positively whether the radial artery was sclerosed or not. In the heart no murmurs were heard, and it was difficult to be sure that the left ventricle was enlarged. There was however a slight but definite accentuation of the second sound at the aortic cartilage which might readily have been overlooked had the patient not been stripped and a careful examination made with the stethoscope. Upon taking the blood pressure it was found to be from 170–175 mm. of Hg. The urine specimen examined at the visit was normal, no casts were found. The applicant was seen at his home and the blood pressure measured. It was again the same. He was seen a third time and practically the same systolic blood pressure was found. Under protests from all the agency staff the man was declined. Two years later he died of apoplexy. The man was angry at being refused. Instead of looking the matter squarely in the face he thrust aside the idea that there was anything the matter with him. He had never had one ill day in his life, his forebears had lived to ripe old age, and he was sure that he knew more about himself than the examiner.

Had this applicant showed a sense of reasonableness he should have been grateful to the doctor for calling his attention to a condition which surely would sooner or later prove either fatal itself or lead to some fatal lesion. It was learned that this man had gone directly to his family physi-

cian who laughed at such nonsense as had been told the (now) patient by the examiner.

Another illustration of a slightly different type of case is afforded in the following history.

A man of fifty years of age, five feet ten in height and 164 lbs. in weight, was brought for examination. In his youth there was a history of a mild attack of scarlet fever. He was almost a total abstainer, rarely taking liquor in any form. Physically he appeared to be an excellent risk. However, on examining the heart it was found that there was slight hypertrophy with an accentuated second aortic sound at the base, and the blood pressure was 180 mm. of Hg. Some sclerosis of the radial arteries was found. One company had refused him on account of albumin in the urine. There was none in the first specimen which was passed while in the office. The specific gravity was 1014. A morning specimen was obtained and contained a trace of albumin. Several specimens were then examined. Some contained albumin, some had no albumin content. The man was declined; no protests from the agent as albumin had been found. There was something tangible in that. Had the applicant been refused on account of his high tension, sclerosis of the radials, and slightly enlarged heart there would undoubtedly have been protests. And yet an applicant revealing such a state of the cardiovascular system without albumin in the urine should unhesitatingly be declined. Attention has been called to hypertension as an early, and some think an invariable, sign of chronic nephritis. My own experience has confirmed me in the belief that in hypertension the kidneys are always the seat of chronic interstitial changes. Careful palpation of the radial and brachial arteries will in every case reveal more or less thickening.

There is yet another group of cases which the examiner sees as healthy subjects, namely those cases of sclerosis of

the peripheral arteries without sclerosis of the aorta and without high tension. In such cases the radials, brachials, temporals and other superficial arteries are readily palpable, sometimes even revealing irregularities along the course of a vessel. Such cases are not subjects for insurance. The recognition of such a condition is of great importance to the one who has it and he should be urged to go to his regular physician for thorough examination. Should the physician ridicule the idea, as has happened to me more than once when I was actively engaged in insurance work, the examiner has done his full duty to the company, the applicant and himself.

A life insurance examiner has a difficult position to fill. He has four people to satisfy; the applicant, the agent, the medical director and himself. The straight and narrow path of strict honesty is his only salvation. By being honest with himself he necessarily gives a square deal to the other three parties.

No applicant who has palpable arteries or hypertension can be considered a first class risk. It cannot be denied that men with arteriosclerosis live to an advanced age and may even outlive those who have apparently normal arteries, but the average life expectancy at any age for an arteriosclerotic is less than that for a normal person. The apparently healthy applicant who learns for the first time when examined for life insurance that he has the early or moderately advanced signs of arterial disease, should thank the agent and examiner for showing him the danger signals ahead. The sensible man then orders his life so that he puts as little strain on his heart, arteries, and kidneys as possible and may add many years to his life.

It is on account of this very insidiousness of onset that I have elsewhere urged as a prophylactic measure the examination every six months of all persons over forty years of

age. I am more and more convinced that it is of vital importance to the health of the public.

As I have remarked, the average man consults his dentist at least once a year so that no tooth may be so far diseased that it cannot be saved. It is purely a means of preserving the teeth. Why not do the same with the whole body? Of what use is it to save the teeth and lose the body? It seems to me that the great army of life insurance examiners are in an enviable position in their ability to add years of life to many men and women. I doubt if they realize their importance in the campaign for health. I should urge life insurance companies not to employ recent graduates unless they have had at least a year's hospital experience. For the company as well as for the individuals I believe that there is a prognostic sense which the examiner should have and this can only be acquired by experience.

I believe that arteriosclerosis and hypertension are increasing for the reasons which have been given in another chapter. There can be no doubt that when these conditions are recognized long before symptoms would naturally supervene, men and women would not only live longer but also die more comfortably and many very likely would be carried off by some disease having no relationship whatever to arteriosclerosis. Slight enlargement of the heart downward and to the left, accentuation of the second aortic sound at the base, a full pulse, arteries which are palpably thickened, increased blood pressure are signs to which attention must be paid. In the great majority of cases they mean one of two conditions, chronic nephritis or sclerosis of the abdominal aorta.

When the peripheral arteries are palpable they are not always sclerosed. The radial artery, the one usually palpated, may lie very close to the bone in a thin person. Under these conditions the artery can be easily felt. It is

better then to palpate for the brachial as it lies beneath the inner edge of the biceps muscle. Should this artery be felt then very probably sclerosis is present. Opinion as to whether or not sclerosis is present, when it is slight, may differ. It is difficult at times to say definitely. Should such be the case the applicant should be most carefully questioned as to his family and past history, the heart should be carefully outlined by percussion and the blood pressure should be taken, both the systolic and diastolic pressures. The urine should be examined with particular care. I am aware that the average examination for life insurance is not made with the care which is bestowed upon a patient. Yet I see no reason why the same attention to detail should not be given in one as in the other. The examination of the great majority of applicants can be made in a short time, as there is no question of latent chronic disease. When the exception turns up he should be given a searching examination and a full report should be sent to the Medical Director. Only in this way will it be possible to weed out the undesirable risks.

On the surface it does not seem to require any great diagnostic acumen to be a life insurance examiner. In the old days of many of the companies there were no examiners. The applicant was brought before the president or other appointed official and he was passed or rejected on his general appearance. This has changed, and now the Medical Department with its scores of examiners in the field is a well organized department.

It seems to me that the examiner should be an exceedingly able diagnostician and prognosticator. There is no telling when he may be called upon to pass judgment on a borderline case. From personal experience I know how difficult it is to make a decision in some cases. These suspicious cases after a careful examination had better be passed by

the examiner and a supplementary report sent to the Medical Director containing unbiassed details. But no applicant with readily palpable arteries, even though the blood pressure be normal, should be considered a first class insurance risk.

CHAPTER XIII.

PRACTICAL SUGGESTIONS.

The time spent in obtaining a careful history of a case is time well spent. Often the diagnosis can be made from the history alone, the physical examination merely adding confirmation to the data already obtained.

The younger the patient who has arteriosclerosis, the more probable is it that syphilis is the etiological factor. A denial of infection should have little weight if the history of possible exposure is present. Miscarriages in a woman should arouse the suspicion of lues in her husband.

There are various ways of examining a patient but there is only one right way; the examination should be made on the bare skin. However skillful one may be in the art of physical diagnosis, he can gather few accurate data by examining over the clothes even if he use a phonendoscope.

The immoderate eater is laying up for himself a wealth of trouble at the time when he can least afford to bear it. The ounce of advice in time is worth more to him than the pounds of medicine later.

It is a wise maxim never to drive a horse too far. Apply that to the human being and the rule holds equally well.

There may be no symptoms in a case of advanced arteriosclerosis. Do not on that account neglect to advise a patient in whom the disease is accidentally discovered.

Many a man owes a debt of gratitude to the life insurance examiner. He rarely feels grateful.

When a competent ophthalmologist refers a case to a general practitioner with the statement that he believes from the appearance of the fundus of the eye that arteriosclerotic

changes are present over the body, the case should be most carefully examined. The earliest diagnoses are not infrequently made by the ophthalmologist.

It is the part of wisdom never to have such a firmly preconceived idea of the diagnosis that facts observed are perverted in order to fit into the diagnosis. Let the facts speak for themselves.

Beware of the snap diagnosis. Even in a case of well-marked arteriosclerosis when the diagnosis seems to be written in large letters all over the patient, go through the routine. Nine times out of ten this may seem needless. The tenth time it saves your conscience and reputation. Always consider that you are examining a tenth case.

Gradual loss of weight in a person over fifty years old should arouse the suspicion of arteriosclerosis.

Do not call the nervous symptoms displayed by a middle-aged man or woman neurasthenia until you have ruled out all organic causes, particularly arteriosclerosis.

When palpating the radial artery, always use both hands according to the method already described. Pay attention to the superficial or deep situation of the artery.

The examination of one specimen of urine does not give much information, especially if it should be found to contain no abnormal elements. Fairly accurate data may be gathered from the mixed night and morning urine; most accurate data from the twenty-four hour specimen. To be of any real value there should be frequent examinations of the day's excretion.

In measuring the day's output a good rule is as follows: begin to collect urine after the first morning's micturition and collect all including the first quantity passed the next morning. It is best to examine the centrifugated urine for casts even though no albumin be present. It is useless to look for casts in an alkaline urine.

Casts are not infrequently found in chemically normal urine from a middle-aged patient.

Blood pressure readings should always be taken with the patient in the same posture at every estimation. At the first examination it is advisable to take readings from both brachial arteries. Let the patient sit comfortably and relax all muscles.

As a rule there is no anomaly of the urinary secretion, yet one must constantly note the amount passed in twenty-four hours and the frequency of micturition.

Differentiate as soon as possible between the uncompensated heart caused by valvular disease and that caused by arteriosclerosis. There is a difference in prognosis. Both give the same symptoms, and are treated similarly until compensation returns; thereafter the management of the two forms is different.

Aortic incompetence that comes on late in life is generally the result of curling of the free margins of the valves caused by arteriosclerosis. Prognosis is grave because of the fact that the heart muscle also is the seat of degenerative changes and compensatory hypertrophy is established with difficulty.

When laying down a regime for a patient, consider his disposition, and individualize the treatment. Remember that exercise is an essential feature of the hygiene of the patient's life but do not forget to be explicit about the amount and character of the permissible exercise.

In the prophylaxis of arteriosclerosis, a rational mode of living is the all-important factor. As a rule, the less meat one eats, the less is the liability of arterial degeneration as age advances. The exceptions to this rule are many, and probably depend upon the character of the "vital rubber" with which the individual begins life.

The diet in well-marked cases of arteriosclerosis should

be carefully selected with regard to its nutritive and non-irritating character. Animal proteids should be sparingly used. Milk should have an important place in the dietary.

No drug relieves the pain of uncomplicated aneurysm as surely as iodide of potassium.

Iodides frequently upset the stomach. Be cautious in the use of them. The irritable stomach may turn the scales against your patient.

Use cardiac stimulants with care and judgment. If all the valuable ammunition is used up at first, the fight will be lost.

When you want to use digitalis, remember two important points: (1) The arteriosclerotic heart is one scarred with patches of fibrous myocarditis, and hence is no longer a heart that can respond with every fiber. (2) Digitalis contracts the arterioles and thus increases the peripheral resistance.

Remember that in the uncompensated heart morphine not only eases the oppressive dyspnea, but also steadies and stimulates the heart.

See to it that the patient has a daily movement of the bowels. In the early stage try the effect of the mineral waters such as Pluto, or Hunyadi Janos, or artificial Carlsbad salts (Sprudel salts). These last can be made as follows: Sodium chloride, ℥i; sodium bicarbonate, ℥ii; sodium sulphate, ℥iv. Take two tablespoonsful of this in a glass of hot water before breakfast. Should these not succeed, assist the action of the drugs by the use of enemata. The pill of aloin, strychnine sulphate, and extract of cascara, with the addition of a small quantity of hyoscyamus, is a mild tonic purgative. In cases of constipation with high tension, there is no drug as valuable as calomel or one of the other mercurials.

Never give Epsom salts unless copious watery stools are

desired to deplete effusion into the serous cavities or into the subcutaneous tissue

Chronic constipation increases the gravity of the prognosis.

In case of suppression of urine and anasarca, hot air packs are of value. The patient may be wrapped in a hot wet sheet and covered with blankets. I do not believe in administering pilocarpine to assist the sweating.

Remember to treat the patient and not the disease. The careful hygienic and dietetic treatment, combined with the least amount of drugging, is the best and most rational method of treatment.
